The disease occurs in young adults or adolescents with a predilection for males. The onset is gradual with fever, malaise, headache (which may be severe), injection of the throat and at times a slight cough. The fever is remittent and moderate, 101° F. or less, but in some instances reaches 104° or 105°. After these rather vague manifestations have existed from one to two weeks, a general lymphadenopathy ensues and the spleen becomes palpable. The spleen may ocasionally be palpable prior to the appearance of the lymphadenopathy. The leucocyte count, which in the early stages may have been low, normal or slightly above normal, increases, due mainly to a relative and absolute increase of the lymphocytes, monocytes and certain abnormal forms which are described in more detail further on. Abdominal soreness in the umbilical and spleen region is fairly frequent. At times a scanty papular eruption appears on the abdomen or thorax, distantly resembling rose spots. The course of the disease may be from ten to fifty days; this constitutes one of its most variable features. The temperature remains slightly elevated with intermissions to normal even after the lymphadenopathy has to a large measure subsided. Occasionally the disease may exist in epidemic or endemic form. Such an occurrence is described by Tidy (5), who cites an outbreak of twenty-four cases in a school for boys in England.

The nature of the lymph node enlargement requires further elucidation. Usually all the lymph nodes accessible to palpation are found to be enlarged to about thumbnail size or slightly larger, though they never take on the dimensions of those seen in Hodgkin's disease, lymphosarcoma or lymphoid leucemia. The lymphadenopathy may be confined to the nodes behind the angle of the jaw. The nodes are discrete and tender. Their histopathology has been derived from biopsy studies, since recovery was the rule in the reported cases. On microscopic examination there are distortion and even loss of the normal architecture of the lymph node; the lymph sinuses are found distended and in these are found large cells with oval pale staining nuclei. There is frequently lymphoid hyperplasia and polynuclear

*From the Jewish Hospital, Philadelphia.

neutrophile and transitional cells are noted. When, occasionally, eosinophile cells are found, the process may remotely resemble Hodgkin's disease, though the absence of giant cells or Dorothy Reed cells is noteworthy. However, cells of great size containing a single nucleus have been described in some of these lymph nodes.

The blood picture furnishes the most curious feature of the disease. The onset may be ushered in with a leucopenia or the total white cell count may be normal or slightly increased. The lymphocyte count may be noted even at this time to be relatively increased. During the period of enlargement and during the subsidence of the lymph nodes, the total count increases up to 20,000, with the lymphocytes and monocytes as high as fifty to eighty per cent. of the differential count. The cells of the large lymphocyte group make up the greater proportion of the increased lymphocyte count. There are in addition abnormal forms with finely reticulated purplish nuclei and large areas of deep blue cytoplasm. Some of these also resemble Turk's irritation forms. None of these apparently abnormal forms shows granules with the oxydase stains.

The abdominal pain noted in this disease may be caused by several factors. There is usually pain in the left hypochondrium due to the enlarging spleen. There is pain possibly from mesenteric lymph node enlargement and may be the origin of the pain localized by the patients to the umbilical region or to one side of it. In one patient, a young adult female, there was typical appendiceal pain which may have been due to increase in the lymphoid follicles of the appendix or mesenteric lymph node enlargement. Hemorrhagic nephritis is an occasional complication.

Case.—M. J. C., a white male, aged thirty years, whose previous medical history was uneventful, began on May 30, 1924, to suffer from headache, feverishness and lassitude. Constipation was noticeable in the next few days and was unaffected by self-medication with purgatives. He was admitted to the hospital on June 7th, with a temperature of 100° F. and at this time complained of a severe headache and slight abdominal pain; there was no vomiting. A slight injection of the throat was present; no cardiac or pulmonary abnormalities; blood pressure was 110 systolic and 80 diastolic. At this time there was no lymphadenopathy, nor was the spleen palpable. A slight cough began on June 8th. The leucocyte count was 4,700 on June 9th.

June 15th: Headache severe; no rigidity of the neck; no diplopia; no definite Kernig's sign; all deep reflexes were exaggerated. The throat was markedly injected and a short dry cough was noted. The lungs presented no abnormalities; a faint systolic murmur was heard at the mitral area. The spleen was definitely palpable and a few papules somewhat resembling rose spots were present on the lower chest. The leucocyte count was 5,800 on June 16th and the differential count is noted in the tabular outline of the blood picture. Abnormal lymphocytes similar to those described above were noted in the differential counts in the proportion of four to eight per cent. Agglutination tests for Bacillus typhosus, paratyphoid A and B were negative. The blood culture taken on June 13th was sterile and remained so after two weeks. The urine was practically normal with the exception of a trace of albumin.

June 17th: The lymph nodes of the posterior cervical chain became enlarged to approximately one cm. in diameter and involved the occipital and retroauricular nodes. Epistaxis was noted and also abdominal pain to the left of the umbilicus.

June 21st: Headache and somnolence were recorded. A marked lymphadenopathy was present involving the posterior and anterior cervical groups. The epitrochlear and inguinal nodes were enlarged to the size of almonds. The spleen was palpable and tender. The next day (June 22d), the lymph nodes below the clavicles, left axillary, and many suboccipital nodes were enlarged. The lungs were clear. There was a faint mitral systolic murmur. Agglutination tests for Bacillus typhosus, paratyphoid A and B were repeated with negative results.

About June 24th, the lymph nodes appeared slightly smaller. On July 29th, the spleen was barely palpable and the lymphadenopathy had entirely receded with the exception of a palpable submental node. The temperature curve though protracted was not unduly high. From June 11th to June 21st the temperature did not reach normal, the evening temperature ranging from 100° to 102° F. and the morning temperature about 99° F. The temperature became intermittent about June 21st and gradually came down to approximately 99° F. from July 9th to July 12th. Constantly normal temperature was reached July 24th. The febrile course was therefore one of about fifty-five days. There was complete clinical recovery up to the present writing, one year later.

TOTAL AND DIFFERENTIAL LEUCOCYTE COUNTS

	June 9th	*June 13th*	*June 16th*	*June 19th*	*June 21st*	*June 28th*	*July 8th*
Total leucocyte count	4,700	4,600	5,800	7,800	7,300	9,300	8,100
Neutrophiles (per cent.)	49	53	..	59	52	40	35
Lymphocytes (1)	40	27	..	35	38	49	62
Monocytes (2)	11	17	..	4	8	11	3
Eosinophiles	..	3	..	2	2	..	..

1. Includes four to eight pathological lymphocytes in practically all the counts. 2. Includes mononuclear and transitional cells.

In addition to the laboratory tests mentioned previously there were two negative Wassermann reactions. Cultures of urine and stools were negative for the typhoid and paratyphoid group. Though a number of symptomatic and empirical remedies were used, without any particular influence on the course of the disease, it is possible that sodium cacodylate may have had some beneficial effect.

SUMMARY

1. An outline of the characteristic features of acute infectious mononucleosis, is given.

2. The history of a patient with this infection, is cited. The course was one of a febrile illness of fifty-five days, with vague onset; later universal lymphadenopathy, splenic enlargement and lymphocytosis. Recovery was complete with regard to the lymphadenopathy and splenic enlargement; the blood count remained abnormal at the time of discharge.

Spring Hay Fever, Its Causes and Preventive Treatment

RALPH OAKLEY CLOCK, M.D., F.A.C.P.
Pearl River, New York

Vernal or spring hay fever is caused chiefly by the pollens of grasses, particularly sweet vernal grass, June grass (blue grass), orchard grass, timothy and redtop. In the Southern and Pacific states, Bermuda grass and Johnson grass are also important factors. Of minor importance are the pollens of trees, especially oak, ash, cottonwood (poplar), and black walnut; also plantain, sheep sorrel and yellow dock pollens.

The date when hay fever symptoms begin will vary somewhat in different sections of the country, being dependent upon the flowering periods of the hay fever plants which in turn are governed by climatic conditions. The time of bloom of the spring hay fever plants is indicated in the following table:

Fig. 1.—June grass. Fig. 2.—Orchard grass. Fig. 3.—Redtop. Fig. 4.—Timothy.

Cottonwood, poplar	(Populus macdougali)	March to April
Oak	(Quercus alba)	March to May
Ash	(Fraxinus species)	March to May
Black walnut	(Juglans nigra)	March to May
Sweet vernal grass	(Anthoxanthum odoratum)	April to July
Orchard grass	(Dactylis glomerata)	April to August
Plantain	(Plantago lanceolata)	April to October
Sheep sorrel	(Rumex acetosella)	May to July
Yellow dock	(Rumex crispus)	May to July
June grass, blue grass	(Poa pratensis)	May to September
Bermuda grass	(Capriola dactylon)	May to September
Timothy	(Phleum pratense)	June to August
Redtop	(Agrostis palustris)	June to September
Johnson grass	(Sorghum halepense)	June to October

HARMLESS PLANTS AND TREES

The fact that true hay fever is caused by the inhalation of wind borne pollens only, eliminates a long list of insect pollinated plants and trees which are popularly supposed to cause hay fever. These insect pollinated plants comprise alfalfa, aster, chrysanthemum, clover, crimson rambler, dahlia, dandelion, goldenrod, honeysuckle, jonquil, lilac, lily of the valley, mountain laurel (rose bay or oleander), roses, rose of Sharon, spirea, sugar beet, sunflower, white daisy and yellow daisy.

The insect pollinated trees which are harmless in hay fever include the common fruit trees (apple, apricot, peach, pear, plum) and most of the ornamental flowering trees, such as catalpa, crepe myrtle, dogwood, locust and magnolia (1). Moreover, Scheppegrell states that several trees whose pollen is wind borne are negative in hay fever, including the arbor vitæ, cypress, fir, hemlock, pine and spruce.

Hay fever in the late spring and early summer is often erroneously designated rose cold or rose fever. Such a name is a misnomer, for hay fever at this time of year is not caused by rose pollen but by pollen from the grasses.

There are certain insect pollinated plants whose pollen will undoubtedly produce hay fever symptoms if directly inhaled, but such pollens are never found in the air in any great quantity and so are practically not a factor in the hay fever situation. The pollen of insect pollinated plants may precipitate an attack of hay fever under exceptional circumstances—such, for example, as where the flowers are deliberately smelled as might be done particularly by children, or where the plants are grown in great profusion in close contact with the patient, or even in some cases where the flowers are used for room decoration. But such symptoms would not long persist.

Fig. 5.—Catkins of oak (Quercus alba).

Fig. 6.—Blossoms of ash (Fraxinus species).

DIAGNOSTIC TESTS

Scientific workers have devised a simple skin test which will definitely determine the particular pollen to which the hay fever sufferer is sensitive. Before he can rationally treat hay fever, the physician should familiarize himself with those pollens which are prevalent in the vicinity where the patient lives; and he should ascertain the usual date of the patient's hay fever attack, so that he may intelligently select the proper pollens to use for the test. Only those pollens known to be in the atmosphere at the time when the patient experiences the most severe hay fever symptoms need be used for the skin tests.

Pollens which are the cause of the patient's hay fever will produce usually within thirty minutes a white, raised area of the skin which looks like a hive or mosquito bite and which is called an urticarial wheal. This wheal may be as large as one inch to two inches in diameter, but more often is about five eighths of an inch and is usually surrounded by a zone of redness. The greater the irregularity in outline of the urticarial wheal, the greater is the sensitiveness of the patient to that particular pollen. Thus, an urticarial wheal with pseudopods (irregular, radiating portions), is more significant than a wheal of regular outline without pseudopods.

Fig. 7.—Catkins of black walnut (Juglans nigra).

Several skin tests should be made, using those pollens which are known to be most prevalent in the atmosphere at the season when the patient experiences the most severe hay fever symptoms. If the patient is affected by several pollens (as indicated by positive skin reactions produced by more than one pollen), the size of the reactions will distinguish between pollens that affect the patient only slightly and those that are harmful and are responsible for the hay fever symptoms.

Treatment should be given with that pollen which gives the largest sized reaction in the skin test. However, the experience of Scheppegrell (2), Walker (3), Goodale (4), Piness (5), Bernton (6), and others (7) has shown that when a person is sensitive to the pollen of one variety of grass, he will react more or less positively to other varieties of the grass family. Therefore, when the degree of reaction from the common grass pollens is approximately the same, a combination of such pollens may be used as a logical treatment for spring hay fever.

GLYCEROLATED POLLEN ANTIGENS

To Koessler (8) must be given the credit for placing the method of desensitization against hay fever on a scientific basis. He emphasized the fact that aqueous pollen extracts are not stable and rapidly deteriorate in potency after three or four weeks. The observations of Koessler have since been amply confirmed (9).

In 1914 a stable and standardized glycerolated pollen antigen (10) was perfected and the medical profession was thus afforded for the first time a practical means for the scientific treatment of hay fever patients. The glycerolated pollen antigens are prepared in stable solution by extracting the mature pollen grains in sixty-six and two thirds per cent. glycerol and thirty-three and one third per cent saturated sodium chloride solution. Such glycerolated pollen antigens have proved to be remarkably stable and more potent than those obtained by any other method of extraction yet described.

It has been clinically demonstrated that hay fever can in many cases be prevented or alleviated by preseasonal treatment with the glycerolated pollen antigen prepared from the pollen to which the person is sensitive. In 1922 I reported (11) an analysis of 1,578 cases of hay fever treated by physicians in all sections of the United States who had used the glycerolated pollen antigen during five consecutive years. This analysis showed an average protection or relief from symptoms of hay fever in eighty-four per cent. of cases with a remarkable uniformity of favorable results each year in every locality. Subsequently Bernton (6), special expert of the United States Public Health Service, published a very complete description of the most successful methods of treating hay fever. He found satisfactory the method used for the preparation and standardization of glycerolated pollen antigens. His experience in the use of these antigens in the treatment of hay fever is confirmatory of my observations.

FIG. 8.—Catkins of cottonwood

POLLEN TREATMENT

Having determined by diagnostic skin tests the pollens to which the person is sensitive, preseasonal treatment is carried out by giving a series of doses of the glycerolated pollen antigen prepared from the corresponding pollen that gave the maximum positive reaction in the test. As already pointed out, however, if the skin reactions from the grass pollens are approximately of the same intensity, an antigen prepared from a mixture of such pollens may be used for treatment. The antigen is administered subcutaneously, preferably in the arm over the insertion of the deltoid muscle.

The object of the pollen treatment of hay fever is to produce a definite tolerance or desensitization to the pollen protein of such degree that the patient can tolerate any amount of air borne pollen as long as the pollen is in the atmosphere—that is, during the pollinating season of the plant.

For many years satisfactory results have been obtained in about eighty-five per cent. of cases by giving a series of fifteen doses of pollen antigen at intervals of forty-eight hours, starting the treatment about five weeks before the date of the expected attack of hay fever. In recent years, however, the tendency has been to make the pollen treatment of hay fever more intensive: first, by using much shorter intervals between doses than were formerly considered satisfactory; second, by using larger terminal doses; and third, by making the treatment both preseasonal and seasonal, continuing the high doses through the height of the pollinating season of the hay fever plant. This intensive form of treatment yields results that are even more satisfactory than those obtained by the former plan of using longer intervals: pollen tolerance or desensitization is brought about more rapidly, reactions are fewer, and a higher percentage of complete protection against hay fever symptoms is secured.

OUTLINE OF INTENSIVE TREATMENT

The intensive form of hay fever treatment is started about two weeks before the hay fever season, beginning with an initial dose of two and a half pollen units and progressively increasing the strength of the doses. For the first two or three days the doses may be given twice a day. After that a dose of pollen antigen is administered daily until a series of fifteen doses has been given. If any dose causes a marked local reaction which persists for twenty-four hours, the next dose is delayed for another day. By starting the intensive treatment two weeks before

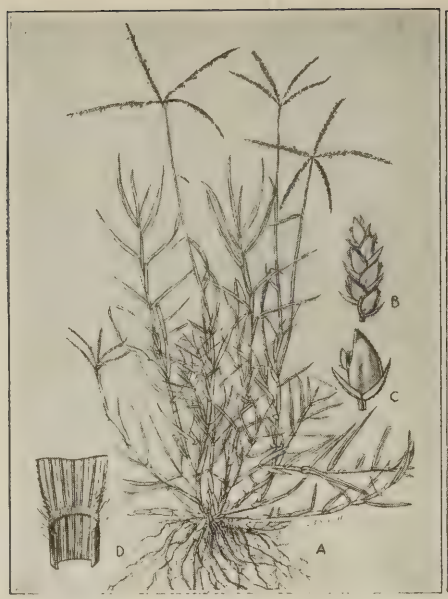

FIG. 9.—Bermuda grass.

FIG. 10.—Sweet vernal grass.

FIG. 11.—Johnson grass.

the hay fever season, a series of fifteen doses administered at daily intervals (or twice a day for the first few doses) can usually be completed by the time the hay fever season begins. Then four or five higher doses may be given at intervals of three or four days in order to give the patient the maximum protection during the height of the pollinating season of the hay fever plants. The terminal dose is two thousand or even three thousand pollen units.

Clinicians have found that by using this intensive method of treatment, the doses are as well if not better tolerated than when longer intervals between doses are used. The intensive form of pollen treatment in which the doses are given once or twice daily has been favorably reported by Brown (12), Bernton (13), and Kahn and Grothaus (14). In comparing the intensive treatment with the previous method of using longer intervals, Kahn and Grothaus state: "It is our experience that the twice a day or daily method of giving treatment which we have used for the first time this year is far more satisfactory to all concerned. . . . Reactions seem to us fewer by this method, and tolerance far more rapidly secured, and relief to seasonal cases is infinitely more prompt."

SUMMARY AND CONCLUSIONS

1. Spring hay fever is caused chiefly by pollens of the grasses, the more important ones being sweet vernal grass, June grass, redtop, orchard grass, timothy, Bermuda grass and Johnson grass. Of minor importance are the tree pollens (oak, ash, cottonwood and black walnut), and the pollens of plantain, sheep sorrel and yellow dock.

2. Diagnostic skin tests should be applied to determine which pollens are the cause of the patient's hay fever symptoms. Only those pollens known to be in the atmosphere at the time the patient experiences the most severe hay fever symptoms need be used for the skin tests.

3. Glycerolated pollen antigens, prepared by extracting the mature pollen grains in sixty-six and two thirds per cent. glycerol and thirty-three and one third per cent. saturated sodium chloride solution, have proved remarkably stable and more potent than those obtained by any other method of extraction yet described.

4. It has been demonstrated clinically that the use of glycerolated pollen antigens affords a high degree of protection against hay fever symptoms.

5. The intensive treatment comprises much shorter intervals between doses than were formerly used; larger terminal doses; and continuing the high doses through the height of the pollinating season.

6. The intensive form of pollen treatment is started about two weeks before the hay fever season. For the first two or three days doses may be given twice a day. Then a dose of pollen antigen is administered daily until a series of fifteen doses has been completed, usually about the time the hay fever season begins. Four or five higher doses are then given at intervals of three or four days to give the patient the maximum protection during the height of the pollinating season.

7. Beginning with an initial dose of two and a half pollen units, the doses in the intensive treatment are progressively increased in strength up to terminal doses of two thousand or three thousand pollen units.

8. The intensive plan of pollen treatment possesses certain distinct advantages: a, pollen tolerance or desensitization is brought about more rapidly; b, reactions are fewer; c, and a higher percentage of complete protection against hay fever symptoms is secured.

9. The method herein described of giving intensive treatment with glycerolated pollen antigens each year before the hay fever season and continuing into the hay fever season seems to offer the best means for the prevention of hay fever.

10. It is no longer necessary to forsake one's business during the hay fever season and journey to a so-called hay fever resort. Intensive treatment with glycerolated pollen antigens now affords hay fever sufferers practically complete protection, so that they can continue to transact their business in their accustomed surroundings.

A Psychoanalytic Introduction to a Study of the Conduct Disorders of Lethargic Encephalitis*

With Outline of Plan for Psychosocial Reconstruction

L. PIERCE CLARK, M.D.
New York

(*Continued from page* 598)

That the ego organ is deeply wounded is shown by the oral and anal eroticism (sadism) which almost invariably obtrude themselves in every severely marked case of encephalitis. In mild cases the dejection and sadness cover, perhaps, the greater part of the clinical picture, but the awareness of destruction of the most highly estimated functions of the ego—the intellect, moral and esthetic sense, ability to create, etc.—must engender a feeling of impoverishment of the whole personal worth (the narcisistic libido). As we know, an equal mutilation of the peripheral system (such as the actual loss of one or more organs or limbs) may still permit the withdrawal of object libido to the ego, and the latter may absorb the bodily defect by the psyche compensating in other permissible activities, in philosophic resignation, humor, pride, defiance, and even scorn. But what may the ego cling to in the presence of gross injury to the very organ by which it operates these egoistic satisfactions, thereby losing its own self respect and self esteem? This is the problem of the poor encephalitic, wrecked in both body and mind structures by which we may equilibrate a changed outer world, or better still, an ego no longer able to adapt to the former outer conditions.[1]

From psychoanalytic teachings we all know that one is born with the biological expectation of unconditional omnipotence, to which a wish free existence within the mother promised. The care and attention which is given to the new born child permits him in great measure to continue this feeling of allpowerfulness, especially if he adjusts to certain simple demands. Next he comes to the position of imagined omnipotence and later to the same condition which is accentuated by the use of certain types of magiclike movements and gestures which seemingly furnish a means of communication with the external world. Very soon, however, he comes to the stage of development of recognizing that certain factors in the outer world have limits. This has been outlined by Ferenczi (1) as a basis of his reality principle separating personal wishes and desires from uncontrollable reality. Cultural adaptations demand still more the renunciation of maintaining in an isolated form the narcisistic self and there is then a compulsive recognition of reality. The outer world then requires of the adult not merely that we take a logical view but that he shall assume an attitude of obedience to these realities, that he shall be attentive, prudent, wise, and at the same time moral and esthetic. Situations arise where he must behave with considerable selfsacrifice even to the point of great personal loss. This whole principle of development of the individual from the most primitive state to that most highly required by society does not occur spontaneously but really under the constant guidance of the repressive forces of society. Thus there takes place a continual procession of identifications with the social agents requiring repression, and withdrawal from such identifications and the formation within the individual of individual patterns of identifications which form the different selves aggregated in his own personality. In the course of this development the ego ideal continually demands more amplitude with renunciations of these identifications and it is, according to Freud, that ego nucleus which behaves as the subject which makes as the object of its criticism the remaining ego that is largely narcisistic and is the beginning of conscience, the censorship by which reality is tested, and the instinct of self regard, etc. Every new capacity which one attains means the fulfilment of an ideal and serves a practical benefit and enlargement of the ego, and a narcisistic satisfaction as well; there is an increase of the feeling of self and the enlargement of the ego stature which had been on the point of being greatly diminished through the unfulfilled ideal standards. A corresponding development can also be held for the object libido which also must pass through certain educational repressions and though it is not as severe and rigid a discipline it must learn to avoid at least gross defects in sexual adjustments, such as incest and certain perversions; therefore even the object love must be "just to the ego" and must conduct itself in accordance with the views and benefits of the narcisistic self respect. This is in brief a onesided consideration of certain developmental phases of the ego which are our immediate concern in the problem we have in hand with this acute narcisistic pathoneurosis of encephalitics.

If in the encephalitic injury certain specific structures are destroyed—which is as surely true as in the metaluetic process of paresis although entirely different structures may and indeed are involved —and if self observation sends report to the ego nucleus that bodily processes as well as important psychic functions have been enduringly damaged, the ego nucleus reacts in dejection and despair if not in an actual psychoneurosis. If, however, the adjustment cannot be made at this level, a deeper regression for outlet takes place and the most primitive and grossly forbidden activities are indulged in. If the ego ideal is able to surround itself by cultural education or enliven regressive memories into kinds of activities that furnish satisfaction, then the narcisism is well protected and the progressive decline of the patient's true value may no longer harm him. Hence one sees

*Read before New York Neurological Society, February 2, 1926.

[1] I wish to acknowledge my indebtedness to the work of Hollós and Ferenczi on paresis which has enabled me to make my own views clearer in this individual problem of conduct disorders in post encephalitic children.

but comparatively few out of the large gross number of encephalitics who present enduring conduct disorders or even actual psychoses. In such either the previous ego development has been comparatively sound, or resilient to the ego organ injury, or the injury has not grossly wounded those structures which disable so profoundly the ego ideal. When, however, the lesion injuries those structures immediately subtending the psychic processes of conscious adaptations, the cortex and its thalamic subcortical structures, then the narcisistic libido creeps after these conditions even more regressively until the juvenile or even infantile behaviors are called into action. Nor are the final levels in ego development the only one showing in the behaviors of these encephalitics; all past stages of erotic and libido organizations are revived and placed in the sum total of behavior reactions. Our own cases show this. They are inclined towards incest, homosexuality, exhibitionism, desire for display, and sadomasochism in all degrees. It is as though this type of pathoneurosis, which in the course of development led towards the polar separations of development of the impulses between the ego centre (brain) and the genital, became retrogressive step by step. And the ego, purged of such socalled beautiful repressions through education, was again flooded with all the inhibited eroticism and the oral, anal and urinary polarities of infantile character once more become the integration of behaviors. Thus, the greater their deterioration, the more unrestrained and all powerful these encephalitics become. Hence we must continually envisage the constitutional factors to be determined by analysis, and the traumatic process and its degree of wounding of the developmental levels of the ego organ (the brain). The manner in which the psyche reacts to cerebral injury as well as toxins, how the ego and its libido complement the narcisism behaves under such circumstances, cannot longer be matters of indifference in the study of these cases.

We must remember that those encephalitics in whom the narcisistic type is overpronounced will bear the disease process quite differently from those of the transference type. This fact in itself should be a signal factor in eliminating a very large number of encephalitics from the group exhibiting conduct disorders which we have demarcated as the classic sort. These adolescents with the transference type of libido may escape our great dilemma altogether. The stubborn types of narcisistic neuroses are our main concern and perhaps the transference types may yield to simpler procedures than those we have proposed herein. Empirical rules of types and degrees of structural damage of brain tissues give some clues as to the course and prognosis of the pathoneuroses although all too little attention has been paid in the past to this sort of topical injury to the brain. A stormy pathocerebral process may provoke a more vigorous pathoneurotic reaction, and the clinical outcome in our cases proves this over and again. The traumatic factor certainly is not wanting in throwing a great mobilization of narcisistic libido into the troubled psyche of our encephalitics. It is largely a question of how suddenly and completely the disorganization of the ego nucleus and its correlated structures takes place, as to whether we have a unity in the disorganization of the total conduct or not. The saving out of certain parts of the narcisism that are still relatively sound in adaptations to reality, has made many a clever psychopathologist a real artist in helping these cases where waiting for a more scientific recognition has been impossible. Aggregating the wrecked personality about the remnant ego nucleus and being able to make that portion the dominant and controlling factor, is the psychotherapeutic talisman. If this fails the psychosocial reconstruction fails also, and a panic or outburst succeeds. As Freud, in speaking of paretic processes, states it, in such panics it would seem as if all the psychic energy which has been accumulated in the course of development were suddenly released and transformed into current energy; hence our clinical picture of fury and destruction so unfortunately the classic reaction in our little patients.

Two cases will be given, the first being an attempt to study the effects of training and psychoanalytic reeducation of a child placed in an observation home.

Case I.—E. K., aged ten years. The outstanding problem at the time this girl was placed under observation was her parents' inability to stay in any one apartment owing to complaints about her noisy or socalled crazy conduct and their inability to handle this situation.

The father was mild tempered, intellectual, and a free thinker. He influenced the child through her affection for him, but in spite of his quiet and gentle manner his attempts to interest her in reading and his desire to undertake other forms of constructive treatment were unavailing. The mother was of a phlegmatic temperament; she took a strongly repressive attitude toward the child, and used foods, sweets and personal bribes as rewards for good conduct. Both parents were proud of her quick, responsive mind and her ability to dance, sing and recite. She was frequently allowed to "show off" at public places of entertainment. She fully appreciated her parents' pride in her performances and played them for her own purposes. They became helpless in her hands and she employed her worldly wisdom to this end. The parents showed a corrective attitude toward the child's physical symptoms and led her to believe that they held her responsible for her puffing, shaking and sleeping spells.

The following personal history was obtained: Delivery had been normal. As an infant she had fits of meaningless crying day and night. Repeated physical examinations showed no abnormality. She was a "nervous" child, quick to learn but always difficult and overdemanding. She insisted on having her own way and had frequent fits of mild tantrums. Nevertheless she was greatly liked by her teachers who considered her very bright. At the age of seven, she awoke one morning with shaking attacks; these recurred almost daily. Later she developed attacks of puffing, and still later the sleeping spells appeared. Her tantrum episodes became more frequent and severe and it was found increasingly difficult to make her conform to any sort of discipline. She began to show marked sexual irregularities, indulged in autoerotic acts, and became excited in the presence of boys. Her conduct was further complicated by the fact that she would scream, fight, or throw anything she could lay hands on when not allowed her own way and had to make new adjustments.

Shortly after the patient's arrival at the training school on August 1, 1922, she went into a violent tantrum, but quieted down soon after her parents' departure. The outstanding characteristics noted during the first days of observation are as follows: There was marked restlessness; her hands and feet moved constantly in muscular contractions that had the appearance of various types of habit movements. She wanted to dance, to play, and had sudden changes of mood, with a tendency to run away. She was uncooperative to a degree, refusing to go to bed, or to adjust herself to other matters of routine. She screamed at the top of her lungs, ran out of the house, used vile language, and in fact any disagreement with her immediate desire was sufficient to throw her into a screaming attack and to change her attitude towards the person for whom she had just expressed deep affection to one of great antagonism. The child said, "I am a beast; I do not want to be a lady, I never want to be nice or anything." There was an abnormal appetite. She disturbed and broke up the games of other children, went about hugging and kissing everyone and particularly desired to sit in the laps of the young men in the household. She stuck pins in the cat's ears and showed marked cruelty in her attitude towards the animals on the place. These conduct disorders were accompanied by three distinct physical symptoms: 1, puffing, characterized by an increased respiratory movement which appeared when she was angry or corrected, when she was frightened, or when interested in some pleasurable task; 2, the shaking attack characterized by an exaggerated shivering as if she were having a chill; and 3, the sleeping attack, which came on independent of the other symptoms just noted or was closely associated with the puffing or shaking episodes.

At first the patient's wishes were considered and every effort made to meet her demands half way, but it was soon found that this attitude only made her more restless and exacting, and a different one was assumed. She was given an opportunity to understand that those in charge wanted her to get well, but that she must try to do something for herself, refrain from using coarse language, screaming and running away; that these suggestions were not a matter of personal convenience to those in charge but represented the attitude of society as a whole. This admonition was productive of good conduct for a short time, but another screaming tantrum soon followed. The child was then given another friendly talk in which she was told that the members of the household were not trying to repress her but that good conduct and kindness to everyone would still be insisted on and above all there should be no more yelling. The child looked at her instructor with great hate and said she did not have to be friendly with anyone if she did not want to. She was assured that this was a personal matter which would have to be decided by herself, and that those in charge would continue to do their part in their attitude of friendly interest in her welfare. The following day, after a little talk about her getting her room in order, the patient ran from the house and up the road. No one went after her as was done in previous episodes, and when it began to rain she returned to the house for shelter. Nothing more was said and she made no effort to make her bed, but it was noted next day that she did attempt to put her room in order, saying it was the first time she had ever tried to do anythink like that all by herself. This act of cooperation was performed only with marked resistance. She said frankly that she did not care to be "good" and that she preferred to be alone rather than try to make any adjustments. The child was allowed to stay by herself and do as she pleased. Towards night she voluntarily came to the instructor and said that she wanted to make up. When commended on her change of attitude she said: "I made my bed this morning, and I'm going to be good—no more yelling." As the patient had a good sense of rhythm and was fond of dancing she was given dancing lessons in the hope that they would serve as a satisfactory form of sublimation.

Several attempts to get in closer touch with the patient's emotional attitudes and gain deeper levels of her conflicts by analysis were met with great resistance. She had frequent sleeping spells during such interviews, only giving a word or two about herself sullenly and unwillingly and then falling into another sleep. Her protests varied from, "Why are you asking me all these questions? I don't want to tell you anything," to "I'm hungry; give me something to eat and I'll tell you anything." When the food was supplied she would assume a jocular mood and begin to dance.

After several weeks her behavior showed some improvement. She stopped using vile language openly but occasionally expressed herself in Yiddish, using derogatory terms to belittle those with whom she was displeased. The usual corrective suggestions were applied and she gave a much better reaction toward them. Once during a talk she said, "Don't tell me how bad I was, for it makes me ashamed."

After three months' observation we find the following comment: "This girl's three prominent symptoms seem to be decreasing. Through our interviews and analytical talks her mental attitude has undergone considerable change. She gets along better with the group and is more considerate of their rights. She is more amenable to discipline and shows less of a tendency to tanrum episodes."

Conduct disorders continued but with increasingly longer free periods during the remainder of the child's stay—ten months in all. The child was gradually helped to connect the necessity for selfcontrol and conformity to the needs of the group with her own physical and emotional welfare. To illustrate: At first she objected to remaining quiet in her room until nearly noon, but finally realized that this rest period gave her a better opportunity to get the day started right. She noted that she was not so much troubled by puffing or sleeping spells when this rest was taken and her mental attitude was better. Her desire for food was treated in the same way and her general physical condition showed marked improvement. She made decidedly better social adjustments in every way. Little reprimands that a few months previously would have thrown her into a violent reaction, now seemed to be taken rather good naturedly. Gradually she began to do little tasks about the house, usually without direction. She gave up the idea that she could find some place to live where she could do exactly as she pleased.

(To be concluded)

An Unusual Case of Syphilitic Epididymitis

MIHRAN B. PAROUNAGIAN, M.D.
New York
and JOSEPH WITTENBERG, M.D.
Brooklyn

Syphilitic involvement of the epididymis occurs more often in the secondary stage of syphilis than is usually recognized. Hutchinson (1) says, "Many observers have noted in the secondary stage slight enlargement of the head of the epididymis that rapidly disappears under treatment." Fournier (2) observed eight cases that appeared between four and five months and six cases between five and fourteen months after the chancre, and nine cases that appeared in from two to nine years after the initial lesion. The symptoms in these cases are, however, usually so mild and the enlargement is so slight that they are overlooked by the patient and the physician.

In cases that are recognized clinically, the statement holds good that "Syphilis of the testicle usually involves the orchid alone; and when the epididymis is affected, it generally follows syphilitic infiltration of the orchid proper." As syphilis of the orchid is in most instances a tertiary manifestation, syphilitic epididymitis is clinically apt to be asymmetrical (unilateral) like all tertiary lesions. Keyes (3) gives a history of sixty-seven cases of syphilis of the testicle (including either or both the orchid and the epididymis) in which bilateral involvement occurred in ten.

Syphilis of the epididymis as it is generally found, involves the globus major and in quite a characteristic way. The infiltrated part forms a hard, smooth mass with a sharp edge and fits over the upper pole of the orchid like a helmet. It is distinctly separated from the testis proper by a deep sulcus. Gummatous nodules are rare in the epididymis. Keyes, in the sixty-seven cases mentioned above, found that "syphilis began in the epididymis as a rounded nodule, the size of a marrowfat pea, and progressed by the addition of other nodules in the epididymis and in the testicle in one case."

In our case, the patient presented a bilateral syphilitic epididymitis without involvement of the testes proper, and on one side the syphilitic infiltration was limited to a small nodular mass in the tail of the epididymis.

Case.—Mr. H. M., aged twenty-five, was admitted to the Bellevue Hospital Clinic for syphilis on January 5, 1925. He had acquired a chancre three years previously and had, at that time, received antisyphilitic treatment that was entirely inadequate. This consisted of one intravenous injection of arsphenamine and seventeen intramuscular injections of mercury. Physical examination disclosed tertiary syphilodermata on both forearms, chiefly on the left, and on both legs and thighs, most marked on the right side. The duration of these lesions he placed at three months. At the head of the right epididymis, there was a typical syphilitic helmetlike mass covering the upper pole of the testicle and extending posteriorly half way down the orchid; and a slightly tender, rather irregular mass, the size of a very small hazelnut, was felt in the tail of the left epididymis. The patient had first noticed the enlargement of the right epididymis two weeks previously, and he placed the duration of the small mass in the left at two days. Both orchids were apparently normal. His blood Wassermann was three plus.

While the helmetshaped mass above the right testicle was characteristic of the disease, the nodular

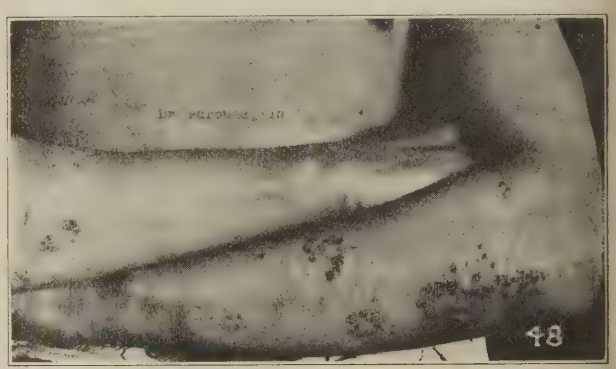

Fig. 1.—Tertiary syphilodermata on forearms of patient.

mass in the tail of the left epididymis required differential diagnosis from, 1, gonorrheal infection; 2, an infection following trauma of the posterior urethra by a urethral sound or other instrument passed into the bladder, or by a too vigorous prostatic massage, and 3, from a tuberculous process, for it is not at all uncommon for a tuberculous process to be present in the epididymis for a considerable time without the patient being aware of it, the infiltration being first noticed by accident.

DIFFERENTIAL DIAGNOSIS

Gonorrheal epididymitis was excluded on the following grounds: while the patient had had a gonorrheal urethritis some eighteen months previously, his urine was clear and his genital tract was found entirely negative on physical examination. Traumatism of the posterior urethra was excluded by the history.

The question of tuberculosis presented greater difficulties, but because of the absence of any signs or symptoms suspicious of tuberculosis in any other part of the genitourinary tract and of tuberculosis elsewhere, and the presence of positive signs of syphilis, we considered this mass in the tail of the left epididymis to be syphilitic and the results of treatment justified this diagnosis.

Some Notes on Cancer*

V.—On Metastases and Other Distance Effects in Cancer

WILLY MEYER, M.D.

New York

(*Concluded from page* 567)

We return to the point where changed cells were being passively transferred from the focus to the margin of the new growth. It is hardly to be supposed that in cases of virulent malignancy the outbound movement of the new cells, considering its haste, should take place in such an orderly manner that the firstborn cells should remain at the head of the procession and the younger generations should fall in line each in their proper turn. More likely there probably will be a general mixup of cell generations, older cells perhaps striking an obstacle which detains them and younger cells being pushed past them. Goldmann (24) (p. 19): "In almost every cancer there are found differences in the modus of cell dissemination."—Thus it may happen that a cell which has only just felt the full force of the focus reaches the margin still in the condition which was impressed upon it at the focus without having undergone changes on the way, there having perhaps not been sufficient time for a division to have taken place in transit. The finest lymph vessels are still of a size sufficient to admit the cancer cell. W. J. Mayo (31) (p. 1256): "Generally, it is the function of the lymphatics as absorbents to pick up . . . the cancer cells which are too large to enter the blood capillaries." If then at the margin this cell be taken hold of by the lymph stream and be carried off, what will happen? In the light of our contention it must be assumed that the cell will divide and that its descendants will keep on dividing until by inward and outward diffusion they have been so changed that the normal lymph has ceased to be a stimulus of division for them.

For the convenience of the discussion we will here introduce for the division enforcing substance in the focus, in part impressed upon the moving cell and carried away by it, the word "noxia," (meaning a noxious fluid, from the Latin "nocere," to damage) an indifferent word which has been selected in order not to prejudice here the nature of the noxious substance to be discussed later. We may say then that the "vagrant" Ewing (32) (p. 83) cancer cell and its descendants keep on dividing until all the noxia originally carried by the vagrant mother cell had been lost to the lymph, and the descendants had eventually been reduced to near normal cells, as normal as their degenerated condition would permit. Erdmann (l.c.): "A tumor cell . . . carries an unknown plus of which it can be deprived by being grown (in vitro) in the normal plasma of a noncancerous animal."—The small quantity of noxia carried originally by the mother cell can, of course, not be believed to prevail against the large volume of circulating normal lymph, and in all probability it will be neutralized or eliminated and what remains of the cells will be phagocytyzed (v. Gaza 33), this whole group of vagrant cells thus disappearing from the circulation. v. Hansemann (8) (p. 185): "Not every dissevered cancer cell produces metastases; they certainly perish in large numbers." Mac Callum (34) (p. 107): "Where a tumor . . . is discharging into the circulation many emboli of its cells, most of these may be destroyed by the activities of the tissue fluids.—Orth (35) (p. 327): "The formation of metastases depends not alone upon the disseminated cells, but also on the individual organism, so that many of the cells remain ineffective."—Hirschfeld (36): "Normal serum is capable of damaging cancer cells."—Greenough (37) (p. 460): " . . . the failure of occasional blood metastases to flourish seems to justify the conclusion that substances in the normal serum are inimical to the growth of cancer cells."

A view differing from our conception is expressed by Owen (38): "A cancer cell adrift in the lymphatic stream is like a message thrown out at sea in a bottle. It may be found years afterwards, who can say when and where?"—It will, of course, most likely land nowhere, being in all probability destroyed long before it could have reached the shore.—Borst (39) (p. 28) calls this period during which cancer cells circulate in the body fluids and are being destroyed therein "the premetastatic phase." But if vagrant cancer cells are thus destroyed, how then can Virchow's (40) (p. 55) observation come to pass that "cancer cells appear capable of being the carriers of . . . substances to distant points?" Borst (l.c.) contents himself with stating in reference thereto that "during the metastatic phase an unknown protective force fails to be effective."—Hirschfeld (l.c.) observes that the serum of animals carrying tumors is not possessed of the faculty of injuring the vitality of tumor cells.—Freund and Kaminer (41) blame the failure to protect on "the absence from the serum of cancer patients of protective substances which are present in healthy serum."

From our point of view, to the contrary, something has been added to the serum by which vagrant cancer cells are then enabled to reach distant points in safety, this something being the noxia impressed upon the loose cells at the focus and by them lost to the serum. The condition of the serum and of the floating cells evidently must be harmonized. What one single cancer cell was incapable of doing, namely, to make an impression upon the general medium, may eventuate 1, when large quantities of cancer cells are more or less continually being disseminated from the focus; 2, when the effect of the release of their noxia into the serum is being increased by the parallel effect of their necrobiosis; 3, when that effect is still further augmented by the also equally directed effect of an abnormal endocrine condition. The latter two

*Received for publication March 16, 1926.

points will be reached for discussion in later chapters. We arrive then at the conclusion that a certain degree of dyscrasia of the body fluids in general would seem to be indispensable before cancer cells can remain alive in them while they are being carried far away from the primary focus. To the same conclusion came Borst (42) (p. 30): "A certain degree of dyscrasia of the body juices must have set in before disseminated cancer cells can stand their ground," also Maresch (43) (p. 17), who writes in 1925: "Present tendencies assign a rôle (in the genesis of cancer) to the hormonal action of endocrine glands, wherewith we have gone back close to the cancer dyscrasia of the ancient humoral pathology. But modern science has risen in a spiral high above the old ideas."

If we now assume the general serum of the system to be in this condition of dyscrasia, if we further assume a massive discharge of cancer cells from the focus, if we also assume their arrival at distant points, and finally assume that they become anchored at the distant points in the stagnation there prevailing or by them created, (another matter for later consideration), what then is likely to happen at these metastatic anchorages? Petersen (20) (p. 699): "The cells which make a beginning with becoming separated from the primary tumor and discontinously invade the organism, most readily succumb to its protective forces. The first metastases of a carcinoma quite frequently recede again in their entirety. Not until the soil in the environment of the carcinoma has been manured with decomposing cancer cells will the subsequently arriving cells have been enabled to take root in that soil."—Lubarsch (44) (p. 304): "The mere dissemination of malignant cells does not suffice to give rise to metastases. The conditions encountered by the vagrant cells at the place where they land is what counts."—M. B. Schmidt (7) (p. 47): "Cancer cells which had been carried into the small arteries of the lung in a condition of vital energy perish therein in large numbers . . . not from their own natural weakness, but under the influence of the special local conditions into which they were transferred."—Wood (45) (p. 6): "If a tumor-carrying animal is massaged and killed at once, the capillaries in the lungs will be found stuffed with cancer cells. If such an animal is kept for a considerable time, only two or three metastases may develop."

It would appear then that the arrival of a greater number of living cancer cells at a given distant point is probably followed by the death of perhaps all of them; thereby they are supposed to manure and thus prepare the soil for a metastasis at this point. Each cell had probably carried along and delivered at the new focus noxia from the primary focus. Thereby and with the aid of the other two factors just mentioned, namely necrobiosis and faulty action of endocrine glands, there would then perhaps be brought about in the stagnation at the new secondary focus a degree of concentration of the noxia closely approaching, if not equalling the degree of its concentration in the primary focus, so that subsequently arriving cancer cells would find at the secondary focus conditions similar to those which they had left at the primary focus. They would therefore continue to live and create and maintain at the new anchorage approximately the same conditions which are believed to have prevailed at the primary focus at the time of its incipiency.

The secondary process thus would seem to offer a chance for studying indirectly the primary process: the transformation into cancer cells of fixed tissue cells exposed to the influence of the noxia and thus, as we said at the beginning of this paper, the chance to argue back from the secondary to the primary condition.

This way of looking at the matter is supported by Virchow (40) (p. 55) who says: "That much can be accepted as definitely established by observation that such a dispersed cell-seminium produces the new tumor not out of itself, that the new nodes do not arise, as one would have been inclined to think, from the disseminated cells themselves, but that at the new focus the preëxisting tissue cells become in turn affected and that from them, through local proliferation, arise secondarily the socalled metastases." On the other hand this view is opposed by numbers of pathologists of the modern school, who do not agree with Virchow on this point. They maintain, to the contrary, that the vagrant cancer cells produce out of themselves the metastases. Thus says for instance Herxheimer (46) (p. 511): "As a consequence of their changed metabolism tumor cells contain toxins which are apt to injure their neighbors (Marchand). These toxins may probably also be of considerable importance in the formation of metastases. Quite likely the disseminated cells bring the toxins along and by means of them make the soil suitable for themselves by killing off the local cells and then, on becoming sufficiently powerful to do so, form out of themselves the daughter tumors, frequently only after numerous vagrant cancer cells have perished while forming metastases." Virchow contends that the vagrant cancer cells by their death indirectly change at the secondary focus to their own cancerous status the fixed tissue cells there present. The modern school on the other hand contends that the vagrant cancer cells kill the fixed tissue cells present at the new anchorage and, having thus manured the soil and having made it fit for themselves to live on, they themselves thereupon become the direct producers of a secondary tumor. The modern view, contrary to our ideas, accords with the conception of the primary formation of malignant tumors by the transformation of normal cells into cancer cells endowed with the supra-normal capacity for active invasion and penetration of neighboring tissue. These cancer cells, concededly more or less devitalized and now likely further enfeebled by what they had undergone during their vagrancy, would then become revitalized and thus for a second time capable of producing a malignant tumor.

If, as we believe, the acquisition of the active powers mentioned was erroneous in the first instance, it is in all probability also erroneous in the second instance. Virchow's view, on the other hand, seems to be in accord with recent experimental results. For instance, Goldschmidt (47), experimenting on spermatogenesis in butterflies, found that upon the death of sperm cells in a follicle the sessile follicular cells immediately began to multiply quite excessively and to show evidences of a most intense metabolism, the process being so precipitate that the local cells did

not divide by mitosis, but that their nuclei were torn apart and fragmented.

In any event the contending opinions appear in agreement on the point that at the new anchorage a chemically changed focus had first to be formed and had to furnish the condition on the basis of which the metastatic growth could then take place.

It goes, of course, without saying, that the noxia with which the vagrant cancer cells were presumed to be charged, must have been in existence at the primary site before it could have been carried away. Where did it come from? There were arriving at the primary site in the incipient stages of the new growth no cells charged with the noxia and capable of parting with it, as happened at the secondary site. The noxia must be supposed to have originated in loco at the primary site. The fact that unlimited numbers of cells issuing from the same spot are all charged with the noxia and have supposedly undergone the more or less identical change, makes it appear improbable that the initiative for the change should have developed independently in each individual cell. The fact seems to argue rather for a common source. The pathological development seems to urge the view that the common source is in all probability a chemically changed focus; not a changed general medium, but a chemical change confined to a small local area and in intimate contact with the changed cells, the tissue adjacent to them being at the incipiency of the process not thus changed. Versé (48) (p. 69): "Surrounded on all sides by normal mucous membrane changed glands are demonstrable the transformation of which from the preformed glandular epithelium can be proved with certainty." Hauser (p. 15): "One can see often a quick transition from the normal to the diseased mucous membrane; quite abruptly both border upon one another."

At this early stage, before dissemination had set in, the changed tissue has been excised *in toto* without a trace of the started process being left behind. The excised tissue, therefore, must have contained with certainty the source of the trouble, the focus.

Circumstantial evidence gained at the secondary site, and the pathology of the case at the primary site make the conclusion almost unavoidable that the original underlying influence at the primary site is probably a localized chemical change of the tissue fluids, confined to a small spot, which is walled off, as we shall see later, from the general medium and which is believed to be the primum movens: a medium in the medium, a chemically changed focus.

In the next following chapter we shall now direct our attention to what the literature contains in regard to the chemistry involved in the problem.

The author's references will appear in his reprints.

A Hitherto Undescribed Cause of Impotence in the Male

MAX HUHNER, M.D.

New York

In my book *Disorders of the Sexual Function,* I said (page 177), "The tendency of late has been to see to it that the young female should know more of sexual matters before her marriage than has been the rule heretofore. This is perfectly proper. It seems to be taken for granted, however, that no such instruction is necessary for the male. It is taken for granted that most men have indulged in sexual intercourse before their marriage, and therefore do not need instruction in this regard."

I have of late had several cases in which the only reason for the supposed impotence was the fact that neither the husband nor the wife knew how to perform the coital act. It has therefore been my custom for some time past to ask every patient coming for impotence who had been continent up to marriage, to lie down on the couch and show me what is the position his wife assumes during the act. In the cases above referred to, the patient would lie with both legs fully extended and parallel, that is, just as in the ordinary sleeping posture. I would ask particularly if the wife had her knees flexed and thighs abducted during the act, but would be fully assured that this was not the case. It can be easily seen that in such position it would be impossible for coitus to take place, and if these unsuccessful attempts are continued in for a long period of time, real impotence may result.

It might seem absurd that instruction should have to be given in this regard, but when I emphasize that I have seen quite a number of cases in which the condition had lasted several years, and during this period the patient had been treated by sounds, electricity, prostatic massage, instillations, etc., for a supposed impotence, we at once see the importance of this investigation.

In some of my cases the patient had been under the care of prominent and excellent genitourinary surgeons as well as neurologists, without the doctors ever guessing the real cause of the condition. In one case even, the patient had been indulging in normal coitus with a prostitute for many years before marriage, but never noticed the position she assumed, and was greatly surprised that he could not have proper intromission with his wife since marriage. Strange to say, I have had two medical men, recently married, who had been continent before marriage, in which the above mentioned cause was the reason for their failure.

It is indeed very gratifying to be able, with a few words of explanation, to cure the condition, especially in those cases where other specialists have failed, and the condition had lasted for several years. The increasing tendency towards continence in young men of late years will undoubtedly increase the number of cases seen, and it therefore behooves every practitioner to be on the lookout for this cause.

Historical Medicine

John Hunter—1728-1793*

R. S. LEADINGHAM, M.D.

Atlanta, Ga.

Abernathy, in his Hunterian oration delivered in 1819 before the Royal College of Surgeons in London, calls John Hunter "the first and great physionosologist or expositor of disease," adding that "the whole history of medical science affords no instance of its promotion by any individual at all comparable with that produced by him." Although this statement has not passed unchallenged, it testifies to the loyalty of his pupils and the esteem in which his works were held by them at a time when their own achievements were being heralded by the scientific world. Anatomist, biologist, naturalist, physiologist, physician, surgeon, pathologist, his composite career marks the boundary line between individualistic efforts in the field of science and eighteenth century beginnings of a more systematized advance. It unites the progress in fundamental sciences begun by the great German physician, Haller, with the more materialistic trend of his own day, to the benefit of both experimental and clinical medicine.

Haller was a physician given to scholarly dissertations, and was enriched and endowed with great intellectual powers. Hunter was preeminently a morbid anatomist, who disclaimed any special talents, remarking that if he had promoted professional knowledge, it seemed to him chiefly because of his disposition to distrust opinions and to examine every subject for himself. Both investigated by experiment the nature of function, and both became exact and comprehensive anatomists. Hunter, however, was the first to perceive that no system of physiology could be perfect that did not equally explain the morbid as well as the healthy actions of life.

JOHN HUNTER

While the practice of surgery afforded him an opportunity for the practical application of his studies in morbid anatomy, his concern for that specialty is exemplified in his remark that "the last part of surgery, namely operations, is a reflection on the healing art. It is a tacit acknowledgment of the insufficiency of surgery. It is like an armed savage, who attempts to get by force that which a civilized man would gain by stratagem. No surgeon should approach the victim of his operation without a sacred dread and reluctance, and should be superior to that popular eclat generally attending painful operations, often because they are so, or because they are expensive to the patient."

John Hunter was born at Long Calderwood, a small estate about eight miles from Glasgow, February 13 or 14, 1728. He was the youngest of ten children, three of whom died in early childhood. His father was apparently in fairly comfortable circumstances. He was sixty-eight years of age at John's birth, and died ten years later, leaving him to the care of an indulgent mother. During the boy's childhood and early adolescence he was allowed to do very much as he pleased, and not compelled to take advantage of the opportunities for study that his position afforded. He was fond of the village games, and led a carefree, unrestrained existence, observant of nature, but lacking in self-control, idle and ignorant. He is spoken of as having little taste for books, preferring participation in the country sports to studies of the elementary branches of knowledge. Speaking of himself, he afterwards said: "When I was a boy I wanted to know all about the clouds, the grasses, and why the leaves change color in the autumn. I watched the ants, bees, tadpoles and caddis worms. I pestered people with questions about which nobody knew or cared."

During these years, however, he is said to have acquired some manual dexterity, and at seventeen went to Glasgow to assist a brother-in-law, who was a cabinet maker, and, like John, more given to convivial habits than to earning a livelihood. Nothing came of this association and he returned home. His brother in law, as a further charge against him, was said to possess certain companionable talents, namely, the unfortunate endowment of a good voice and a musical ear. After becoming bankrupt, he took to teaching music, and became a clerk to an Episcopal society in Glasgow.

While John regaled himself at the country side, his brother, William, ten years his senior, was entering upon a career in London that earned for him a place among the most illustrious men of his day. He had at school acquired a reputation for industry and sobriety, and after five years at Glasgow, at first thought of entering the ministry. Later he applied for the position of schoolmaster at his home, but failed to get the appointment. After this, his friendship with Cullem led to an association in a scattered

*Read before the Medical History Club of Emory University, January, 1926.

country practice at Hamilton. Cullem said of him: "His conversation was remarkably lively and agreeable, and his whole conduct more strictly and steadily correct than that of any other young person I have ever known."

After spending three years with Cullem, William attended a series of lectures delivered by Alexander Monro at Edinburgh, and then in the summer of 1741, at the age of twenty-three, went to London. Here he became assistant to Dr. John Douglas, who died the following year. At the same time he made the acquaintance of Samuel Sharp. In 1746 he was admitted to the corporation of surgeons of London. The next year he was appointed physician accoucher to the Middlesex Hospital, and later surgeon accoucher to the British Lying in Hospital.

The fame of William Hunter without doubt soon reached his home village, and attracted the attention of John, who straightway applied for a place in his brother's dissecting room. We do not know whether he was led to do this because he felt any call to study medicine, or because he sought further opportunities for ribald companionship that a residence in London would afford. William accepted his offer in September, 1748, and two weeks before his course of lectures began, set him to work under the instruction of his assistant, Mr. Symonds. There is no doubt that he did this for no other reason than to give employment to a hitherto idle young man, for John certainly had shown no indication of talent for a surgical career. He was untutored, untrained, and altogether unprepared when William took him in hand and began the process of molding and shaping a useful life from about as unpromising clay as the hills of Scotland could afford. We can imagine his gratification when John first showed his dexterity as a dissector, and became able, within a year, to assist in directing the work of other pupils. He then obtained permission for him to visit the Chelsea Hospital under the tutelage of Cheselden, who, besides being the most celebrated surgeon of his day, was also known as a patron of the fine arts, a friend of Pope, the poet, and the designer of Putney Bridge and the Surgeon's Hall.

Thus John was kept busy between dissecting room and hospital until 1750, absorbing, no doubt, from the association with his brother and professional companions, some of the culture he had thus far little cared to possess. The restraint of polite society at first was probably irksome, but he found opportunity for more congenial fellowship when, as procurer for the dissecting room, he cultivated the society of a rather ill savored company among whom were members of the resurrection squad. To them he was familiarly known as Jack Hunter. How he profited by this companionship is attested by the way in which, several years later, he secured the skeleton of the famous Irish giant, O'Brien. Learning that O'Brien was in poor health, he sent his man, Howson, to watch his movements, that he might, at death, secure his body for dissection. O'Brien, hearing in some manner of the plans, left orders that when he died his corpse should be watched until it could be enclosed in a leaden casket and consigned to the seas. When word came to Hunter of his death, he promptly hurried to the place where his body lay, and bribed the watchers to deliver it to him for fifty pounds. The deal failed to go through, however, until he had paid five hundred pounds; then, in the dead of night, he finally received his prize in a hackney coach. The coffin was filled with rocks and taken out to sea. In order to facilitate his work, and escape detection, the body was quickly cut to pieces and the flesh removed by boiling. The process, unfortunately, gave an undesired brown color to the bones that formed the skeleton which headed his osteological collection.

After Chelselden's death, he studied five years as surgeon's pupil in St. Bartholomew's. Then the question arose as to the line of practice he should follow. William, who was eventually to devote himself to obstetrics, suggested that John should join him in that specialty, but, seeming to recognize his brother's limitations and the handicap of his uncouth ways, he sent him to Oxford. John remained there some two months, and returned to London anxious to secure for himself a chance of election to one of the hospitals, and the opportunity to practise surgery. He entered St. George's as surgeon's pupil, and two years later served as house surgeon. At the same time he was taken into partnership in his brother's school of anatomy. While active in this capacity, his acquaintance with anatomy was quite generally recognized, and his opinion frequently sought by others engaged in anatomical studies. It was then that with Dr. Mackenzie and his brother, he discovered the circulatory relationship between the placenta and uterus. The discussion of the priority of this discovery led to an unfortunate misunderstanding with William when it was published.

In 1759, because of some incipient lung trouble, he was advised to leave London for a time and go South. Accordingly, he secured an appointment as staff surgeon in the Army, and went first to the western coast of France, and then to Portugal with his troops. Here he began his study of gun shot wounds and inflammations, and research in the field of comparative anatomy. His experiments to ascertain the digestive state of a hibernating animal, and the faculty of hearing in fishes, illustrate the simplicity that characterized all of his research work. Taking hibernating lizards and snakes, and keeping them in cool places, he forced food into their stomachs and killed them at intervals to note the extent of any digestive change. To determine the faculty of hearing in fishes, he watched beside a pool in a nobleman's yard, and saw them scatter at the report of a gun fired by an assistant behind him.

In 1763, at thirty-five years of age, he returned to London and began practice as a surgeon. He was without funds, except for his half pay from the Army, and the place he had had with his brother was now occupied by Hewson, who had been taken into partnership soon after Hunter left London. First and second places in hospitals were also filled by very capable men. He was therefore compelled to depend for a practice upon the reputation gained by his previous residence and work. To augment his scanty income, he gave lectures on anatomy and operative surgery to a private class, but, not being a clear and convincing lecturer, had few pupils. Previous misunderstanding with his brother kept him from receiving aid from that quarter, and his show of conscious mental superiority raised bitter enemies and prevented

him from becoming a popular member of the profession. A friend observed to him one day: "Ah! John, you are always at work!" "I am," replied John, "and when I am dead you will not soon meet with another John Hunter."

Intrinsic excellence in his work, and honesty of purpose, however, gave him the most loyal support and friendship of a few who recognized his worth. In writing of his application for appointment as surgeon to St. George's Hospital, he said: "It was not with a view to augment my income either immediately, by the profits of the hospital, or in a secondary way, by increasing my practice, but to acquire opportunities of extending my knowledge, that I might be more useful to mankind." The appointment which he received provided what he desired, attendance upon the living and examination of the dead, besides a share of the pupil's fees and the credit of being on the staff. One of his biographers states that his income never passed one thousand pounds until after eleven years of residence in London. He spent all that he made for specimens for his museum. Although continually at work on some research problem, he had not published anything up to 1767, when he was elected a fellow of the Royal Society, a year before a similar honor was bestowed upon his brother. His first book, the first part of *Treatise on the Natural History of the Human Teeth,* was published in 1771.

In 1773, at the age of forty-three, he married Annie Home, the daughter of Mr. Robert Home, whom he had met while serving in the Army. She was twenty-nine years old, "an agreeable, clever, and a handsome woman, rather fond of gay society," a taste which occasionally interfered with her husband's more philosophical pursuits. It is said of him that, on returning home late one evening, Hunter unexpectedly found his drawingroom filled with musical professors, connoisseurs, and other idlers whom Mrs. Hunter had assembled. He was greatly irritated, and addressed the astonished guests in the following manner: "I knew nothing of this kickup, and I ought to have been informed of it beforehand, but as I have now returned home to study, I hope the present company will retire."

In 1776 he was appointed Surgeon Extraordinary to the King, and in the same year gave the first of his Croonian lectures on muscular motion before the Royal Society. His practice had by this time greatly increased, and from his income he was able to purchase more and more for his museum. The number of specimens soon made it necessary for him to secure new quarters, and he purchased a lease for a plot of ground and erected a building to house them. About the house he had a covered alley way six feet deep with a subterranean entrance, through which he could drag anything from a giant's body to a good sized whale. The burrow opened into the stable yard, in one corner of which was another passage which led to three cellarlike vaults, where he kept his dangerous animals.

In these quarters John Hunter worked, surrounded by his collection, and here he gathered a few choice pupils who came to know him so intimately that among themselves he was known as the "dear man." Jenner was the first to come, and the friendship between pupil and master was very intimate, and lasted throughout Hunter's life. While Jenner was away he kept in close touch with him by letter, and these epistles, portraying the restless, energetic mind, constituted an interesting portion of most of his biographies. One of his letters to Jenner is as follows:

> Dear Jenner: I received yours, and was extremely happy to hear of your success in business. I hope it will continue. I am obliged to you for thinking of me, especially in my Natural History. I shall be glad of your observation on the cuckoo, and upon the breeding of toads: be as particular as you possibly can. If you can pick me up anything that is curious, and prepare it for me either in the fish or flesh way, do it.
>
> Pictures have been very cheap, but the season is now over. There will be but one sale, namely Fordyce's, but I believe all of his pictures are exquisite and will go beyond you or me. Since you wrote to me, I purchased a small landscape of Barrett's of cattle and herd. I gave five pounds, seven shillings and sixpence; it is one of his eight guinea pictures. You shall have it or not as you please. I have one of the same size that I bought of him some time ago.
>
> I saw the young lady, your patient; I do not know well what can be done. Let me hear from you soon.
>
> Ever yours,
>
> John Hunter.

The years from 1772 until his death were very productive. Among the most noteworthy of his publications were: his *Treatise on the Natural History of the Human Teeth; Treatise on the Venereal Diseases; Observation on Certain Parts of the Animal Economy; Treatise on the Blood, Inflammation, and Gunshot Wounds,* the latter upon which his future fame was largely to depend, comprising the results of forty years observation. Other important contributions include the account of his method of treating a popliteal aneurysm, and *The Digestion of the Stomach after Death.*

In 1773, he experienced his first attack of angina pectoris. In 1785, he had his most severe illness, and from that date until his death, the spasms were easily reproduced by the most trifling exertion or mental irritation. He was accustomed to say that his life was in the hands of any rascal who chose to annoy or tease him. In spite of this, however, he continued to enjoy life, and was not oppressed with a fear of death.

In 1792, he contributed his last paper to the *Philosophical Transactions.* It contained the results of his observations on the bee, a work that, it is estimated, required the dissection of four or five thousand specimens. As his practice had so greatly increased, and his health grown weaker, he asked for an assistant at St. George's. It was during an altercation over the appointment of two young men to the hospital, that, on October 16, 1793, he was fatally stricken. His body was carried from the hospital to Leicester Square in a sedan chair. An autopsy was performed, and revealed an extensive sclerosis of the coronary arteries. He was buried in the vaults of St. Martin's-in-the-Fields. On March 28, 1859, his remains were removed to the North aisle of Westminster Abbey.

Hunter left nothing for the care of his family after the payment of his debts but his collection of anatomical preparations, which after three years' delay, the House of Commons voted to purchase for the sum of fifteen thousand pounds. The museum was given first to the care of the Corporation of Surgeons, and later, after the chartering of the Royal College of Surgeons in London, to that body. He

had long before his death, taken, as an associate, his wife's brother, Sir Everard Home; and in 1792, Cleft came to him, and was given charge of the museum. Both of these men played important parts in the disposal of his writings and collections. Home was acting executor, and retained the manuscripts for twenty-three years. He was pressed by the trustees to write a catalogue, but never did so. From the manuscripts, it is charged, he used what he could in his own numerous papers and lectures, and in July, 1823, burned them, asserting that he did this because Hunter, feeling that they were not in shape for publication, desired that they should be destroyed.

In estimating the worth of John Hunter's contributions to science, his biographers credit him with being the first to bring the lights of physiology to bear upon the practice of medicine. His chief attribute of character was his great general mental strength and vigor. He also possessed a talent for observation that was unusually acute and carefully trained by constant application and practice.

Morally, he was a man honest with himself and work, a generous and warm friend, a kind husband, but wanting in control over his passion and temper. He was very liberal in his charges to his patients, and, it is said, he usually let them say what they could afford to pay. The following extract from an obituary in the *Gentleman's Magazine* probably credits him with more talent and understanding than he deserved. It is written: "As a man of letters, independently of his profound scientific studies, he had traced the practice of surgery to the earliest ages. He was well acquainted with every practitioner mentioned by Phiny, with all the Greek and Roman authors who had written on the subject, as well as with every modern one who had contributed to the perfection of the art. As a man well versed in ancient history, the Egyptian chronology was familiar to him as far as related to the antiquity of anatomy." One of his biographers in quoting this extract, states that it would appear as though the writer had purposely selected the weak points of Hunter's character in order to parody them.

The following epitaph composed by his wife was inscribed on the marble tablet placed in St. Martin's Church:

Here rests in awful silence, cold and still,
One whom no common sparks of genius fired;
Whose reach of thought Nature alone could fill,
Whose deep research the love of Truth inspired.

Hunter! if years of toil and watchful care,
If the vast labours of a powerful mind
To sooth the ills humanity must share,
Deserve the grateful plaudits of mankind,—

Then be each human weakness buried here
Envy would raise to dim a name so bright;
Those specks which in the orb of day appear,
Take nothing from his warm and welcome light.

Dioscorides and Hydrophobia*

HONORABLE WILLIAM RENWICK RIDDELL, LL.D., F.B.S., Edin., Etc.,
Toronto, Canada

NOTES

7. Joannes Lonicerus is unknown to fame and the dictionaries.—See Note 17, post.

8. Anchusa, Lib. 4, c. 21, pp. 299, 300. Spina alba, Lib. 3, c. 12, p. 203; Calaminth, Lib. 3, c. 33, p. 217; Peucedanum, Lib. 3, c. 74 p. 242; Cedrus, Lib. 1, c. 89, p. 51; Gagates, Lib. 5, c. 92, p. 418; Lychnis, Lib. 3, c. 96, p. 253; Elaphoboscum, Lib. 3, c. 64, p. 236; Rhamnus, Lib. 1, c. 102, p. 58, Sativa angelica, Lib. 3, c. 63 (n), p. 236; Mus. Lib. 2, c. 61, p. 116; Swallows, Lib. 2, c. 47, p. 113; Pumice, Lib. 2, c. 173, p. 191; Dipsacum, Lib. 3, c. 11, p. 293; Polemonia, Lib. 4, c. 7, p. 293; Sacra Herba, Lib. 4, c. 51, p. 314; Mandragora, Lib. 4, c. 65, p. 324; Taxus, Lib. 4, c. 68, p. 327; Phytuma, Lib. 4, c. 114, p. 349, Leontopodium, Lib. 4, c. 115, p. 31457; Mus Araneus, Lib. 2, c. 60, p. 116; Urina canina, Lib. 2, c. 73, p. 125; Psyllium, Lib. 4, c. 60, p. 320.

9. The word is "pituita," phlegm, rheum, one of the four humors.

10. Or tendons.

11. Eudemus or Eudamus, the name of several Greek physicians whose identification is very difficult.

12. Themiso or Themison, a celebrated physician born at Laodicea, a pupil of Aesclepiades. He came to Rome about 90 B. C. He took a middle course between empiricism and dogmatism, a real eclectism. He may be regarded as the founder of the school of Methodists which indeed became as dogmatic as the Rationalists. Themiso insisted on dyscrasia of the whole body not of the humors alone as the cause of disease. He was the first to use leeches which he applied to the temples in disorders of the head. See Anthon, *op. cit.*, p. 1313: Bass, *op. cit.*, p. 140.

13. In Lib. 2, c. 9, p. 99, *Cancri*, Dioscorides says: "The ash of river crabs cremated (exustorum), two spoonsful with about half the amount added of gentian root drunk in wine for three days is extremely useful in bites of a mad dog; in a decoction with honey, it alleviates cracks in the feet and seat, also chilblains and carcinomata; ground raw and drunk with asses' milk, crabs help against bites of serpents and spiders; cooked and eaten with the juice they help those affected with tabes . . . ."

14. Hamulus, a small hook: vulsella or volsella, tweezers, or pincers.

15. Salsamentum properly a salty sauce, but applied to saline washes, lotions, etc. We have an English word, salsamentarious.

16. Theriaca. There were a score of Theriacas and Mithridates without number. Charas gave the formulas for three Theriacas: a. Theriaca Andromachi senioris containing sixty-four ingredients (pp. 225-230). b. Theriaca diatesseron of Diatesseron, Honey and Juniper berries "invented especially for the poor," pp. 237, 238, and c. Theriaca reformata Domini d'Aquin of thirty-six ingredients (pp. 230-237). The first and third contain vipers. Charas also gives the mithridatium Damocratis of forty-eight ingredients (pp. 238-244). All these are prophylactic against and a cure for all poisons.

17. Joannes Lonicerus wrote *Scholia*, i. e. Notes, to the various Chapters of Dioscorides, which Scholia are printed as Addenda in this edition. He points out that Paulus Aegineta advises that before all else, care must be taken to keep the wound open. He says that while the fear of water generally sets in about the fortieth day, sometimes it does not appear for six or even seven months. The scholiast quotes further from this author as to the symptoms, etc., *Scholia*, Lib. vi, cc. 36, 37, pp. 84, 85.

*Read before the University of Toronto Medical Society.

18. Hiera containing colocynth. Hiera is a purgative generally containing aloes and in many cases also colocynth.

19. Dropacism, pitch plaster.

20. Galeni *De Simpl. Medic. Facult.*, ii, 10; p. 356 of Vol. 12 in Kühn's Edit., Leipsic, 1821-1830.

21. Sometimes called belops. See Art. *Aeschrion iii,* in Anthon's *Classical Dictionary,* p. 1,418. This formula met the approval of Galen and Oribasius.

22. Paulus Aegineta, a celebrated Greek physician born at Aegina probably in the 7th Century: he studied medicine at Alexandria and fully accepted Galen's theory of Humors. He was, however, independent in his views and has been considered the equal of or even superior to Celsus; he is the last of the great Greek physicians. Eminent as he was as a physician, he was more so as a surgeon. One of the most interesting as it is the most curious of his Chapters is that on the different kinds of arrows used by the ancients and the wounds they inflicted. His chief work is *An Abridgement of All Medicine* in seven books, which has been frequently republished. In Greek, the Aldine edition, Venice, 1528, and in Latin the Lyons edition, 8 Vo., 1567, with many learned annotations, enjoy the highest reputation. See Anthon, *op. cit.,* pp. 24, 25. Bass, *op. cit.,* pp. 205-208.

23. Oribasius, an intimate of the Emperor Julian, born at Sardis or Pergamus (the birthplace of Galen)—he studied medicine under Zeno and became court physician to Julian and who took him with him to Gaul, A. D. 355, also on his fatal Persian expedition, A. D. 363. He followed Galen so closely in his theory and practice that he was called the Ape of Galen: he appears to have been the first to bleed by scarification: his use of the oil bath was constant, and his treatment of epilepsy by drastic purgatives, colocynth, scammony, hellebore, etc., followed by occipital cupping and sinapisms had a great reputation. He wrote much on medicine, anatomy, etc., but we have no complete edition. See Anthon., *op. cit.,* pp. 924-6;; Bass, *op. cit.,* pp. 185, 186.

24. Lib. 2, c. 39, p. 40. "Take a hair of the dog that bit you."

25. Scholia, Lib. 2, c. 38, p. 29.

26. Lycium, Lib. 1, c. 114, p. 65; Walnuts, Lib. 1, c. 141, p. 87; Metuli, Lib. 2, c. 4, p. 76; Smarides, Lib. 2, c. 26, p. 106; Garnum Lib. 2, c. 30, p. 107; Canine blood, Lib. 2, c. 71, p. 114; Canine urine, Lib. 2, c. 74, p. 125; Honey, Lib. 2, c. 74, p. 126; Plantago, Lib. 2, c. 119, p. 154; Alyssum, Lib. 2, c. 143, p. 169; Onions, Lib. 3, c. 87, p. 249; Cynoglossus, Lib. 3, c. 162, p. 183; Sambucus, Lib. 4, c. 113, p. 348; Acida muria, Lib. 5, c. 13, p. 389; Terra Lemnia, Lib. 5, c. 63, p. 407; Nitre, Lib. c. 78, p. 14; Ash, Lib. 5, c. 82, p. 415.

27. Scholia, Lib. 3, c. 96, p. 52. *"a,"* privative, and *lussos* (Latin form lyssus), mad.

It may be of interest to give the views of the celebrated Van Helmont on hydrophobia, its cause and treatment. In a volume published in London in 1683 entitled: *The Paradoxal Discourses of F. M. Van Helmont concerning the Macrocosm and Microcosm: or the Greater and Lesser World and Their Union,* he discusses amongst many other things—*de omnibus et quibusdam aliis*—the Dog and his love for his Master: at pp. (78) (79) we read:

"And is it not worth our taking notice, that when these internal waters in a dog, through divers causes, as hunger, over great heat or cold, are turned the contrary way and disordered, so that he cannot take his due rest; the Image of Love he had for his Master, is turned to Enmity; and by this means he grows mad, and becomes shy of the outward water (forasmuch as he is at enmity with his inward water the images formed out of it) so that he hates it, and cannot endure it; and that because his internal disordered waters are thereby put in motion? And whilst he is thus distempered, if he chance to bite another dog, beast, or man, or if he do but touch their skin with the foame of his mouth, immediately the spirit of his perverted and disordered waters and image, doth enter into them, and causeth the same disorder in their waters, so that they in like manner become shie of the outward water.

Furthermore, it hath been found by experience, that the best means for curing this distemper is lightly to burn or cauterize the skin of the bitten man or beast with a small red hot iron or copper, and by this means to put them into a fright of fire, or else by plunging them well under water: for thus the outward fire or water spirit of the great world which stands in its due and right order, will be predominant over and master the disordered spirit of the little world, and turn about and set to right the disordered waters of the same. And is not this well worth our animadversion and consideration?

Osgoode Hall.

A Rare Medical Book.—The Japanese Correspondent of the *Journal A. M. A.,* in a letter dated March 16, 1925, writes as follows concerning a rare Dutch medical book, Kulm's *Tabula Anatomica,* which, he says, was destroyed in the earthquake in Tokyo in 1923:

The old volume was the property of Prof. Dr. Matao Nagayo, director and professor in the Tokyo Imperial University. Nearly one hundred and fifty years ago, in the Tokugawa era, the book was brought to Japan by a Dutch missionary. At that time people here knew very little about European medical science. It was therefore quite an epoch making event in the medical history of Japan when Dr. Gempaku Sugita and his friends, earnest students of Dutch medical science, went to the postmortem of a criminal held at Kozuka Common, one of the execution grounds, in the suburbs of Edo (now Tokyo) and there studied anatomy, marveling at the exactness of the illustrations in the foreign book. Dr. Gempaku's account of his difficulty in translating the book, with his poor knowledge of Dutch, is related in his autobiography entitled *Rangaku Kotohajime* (Pioneering in Dutch Science). His *Kaibo Shinsho* (New Anatomy) was the first translation in Japanese. A century elapsed, and Dr. Sensai Nagayo, father of Professor Nagayo, happened to get possession of the original book of *Kaibo Shinsho.*

He valued it a great deal more highly than any other book in his library and would not part with it, though he sent it to an exhibiiton in Dresden and another time displayed it in the Far East Tropical Medicine Congress held in Java. Great was his son's sorrow when the heirloom was burned in the earthquake disaster. But his joy was even greater when he received another copy of *Tabula Anatomica,* the gift of the Dutch medical scholar M. Van Roemer, exnaval surgeon, of Java. He has written to Professor Nagayo that he was unable to attend the Far East Tropical Medicine Congress held in Japan last autumn, and that he sent the book to promote friendly relations between Japan and his country. In his letter of thanks the professor said that his joy was as if one's dead child had come to life again. He took the volume to the annual memorial service of dead medical sages held at Kozuka Common to show it to his friends.

It is reported that after consulting with Dr. Kitasato and Dr. Miyakawa he has decided to donate the invaluable book, rare even in Holland, to the new library of the Tokyo Imperial University, now in course of reconstruction.

Music as a Therapeutic Agent.—Music as a curative factor in disease has long been discussed by physicians, but its practical use in hospitals has been generally disregarded. During the Crimean War, Florence Nightingale requested music in the hospitals, and the "corridor singing" established in 1860 in St. Thomas's and other London hospitals grew out of her belief in its efficacy.—*Nation's Health.*

Oral Focal Infection as a Cause of Systemic Disease*

EDWARD C. ROSENOW, M.D.,

Rochester, Minnesota

It is my purpose to discuss briefly in this paper, the development of the theory of focal infection and elective localization and to emphasize certain findings commonly overlooked which demonstrate the mechanism involved in the production of disease in remote parts from foci of infection, and the reasons for clinical success or failure through the application of the principles involved in focal infection and elective localization.

Nowhere in medical history is the value which comes from combined clinical observation and experimental inquiry better illustrated, than in the development of our knowledge of focal infection. Notwithstanding the repeated suggestions made in previous years concerning the etiologic relationship, especially between acute localized infection and grave systemic disease, the medical and dental professions as a whole remained indifferent until Billings and his coworkers made their clinical observations and correlated experimental studies in animals demonstrating the importance of localized infections, even though small and symptomless, as common sources of various systemic disorders. The broader conception of this interrelationship, well expressed by the term "focal infection," may therefore be regarded as having originated in recent years. I count myself fortunate in having been associated with Dr. Billings and to have been able to participate in this earlier work in Chicago, and to have had the opportunity to continue my investigations in conjunction with clinicians at the Mayo Clinic in Rochester.

Aside from affording information concerning the pathogenesis of a series of diseases formerly not well understood, the work gave medical science a therapeutic principle of the utmost importance. Numerous reports on the relief of symptoms following the removal of foci of infection soon followed. The scope of this influence may be judged by the voluminous literature on focal infection which has since appeared throughout almost the whole civilized world. The benefits which have already accrued directly or indirectly are almost beyond calculation. It is not surprising that much speculation and opinion, often insufficiently supported by facts, have been indulged in, both by clinicians who often have little conception of the real significance of experimental studies and by purely laboratory workers who know so little of the clinical applications of their findings. All of the men who were associated with Billings and who did the experimental work had had both clinical and laboratory training and had intimate knowledge of the condition of the patient under investigation. Both types of study have value but this could be greatly increased if the studies in this field could be made in collaboration or in closer cooperation. Such combined study is the crying need today, in the further working out of this problem. How much more might be accomplished if the many operators in the dental field, particularly root canal experts, exodontists and dental surgeons, and specialists generally, could correlate their clinical and röntgenological findings with results of equally expert bacteriological and experimental studies in animals than by attempting to evaluate the safety of the various procedures, such as root canal work, by mere clinical observation, as is now almost universally done. Through splendid cooperation of clinicians, experimental results have been obtained in my own work that go far towards establishing important relationship of focal infections and elective localization to each of the following diseases: endocarditis, rheumatic fever, erythema nodosum, herpes zoster, intercostal neuralgia, epidemic parotitis, appendicitis, ulcer of the stomach, cholecystitis, pancreatitis, acute and chronic arthritis and myositis, neuritis and sciatica, nephritis, pyelonephritis and nephrolithiasis, iritis and other diseases of the eye, and in various diseases of the central nervous system.

The inability of certain investigators to corroborate my results would seem to be explainable on the ground of the improper selection of cases and material for study or of insufficient attention to technical details, as pointed out especially by Gay and Haden. The early results in studies on ulcer were corroborated by Hardt and Helmholz, those on iritis by Irons, Brown and Nadler, and those on cholecystitis by Brown. The elective localizing power of streptococci and colon bacilli from urinary infections has

*Read before the annual convention of the American Stomatological Association, April 5-7, 1926, at the New York Academy of Medicine.

been demonstrated by Helmholz and Beeler. The results in the study of ulcer and arthritis have been fully corroborated, extended, and controlled in my laboratory by Meisser, with streptococci isolated from infected teeth in the study of ulcer of the stomach and arthritis, by Nakamura with streptococci isolated from extirpated tonsils, and by Giordano with streptococci isolated from infected teeth and tonsils after death of the patient. My methods have been used successfully in a study of the etiology of pyelonephritis and ulcerative cystitis by Meisser and Bumpus; by Moench in a study of the etiology of endocervicitis, in which she demonstrated that this condition is often due to partial tension streptococci and may be a common cause of arthritis in women; and in a study of the etiology of chronic ulcerative colitis by Bargen. Price, working independently, has also reported corroborative results. The work on iritis and other diseases of the eye, on ulcer of the stomach and on pyelonephritis, as concerns dental foci especially, has been verified and greatly extended independently by Haden. Through strict attention to technical details he has even succeeded in producing onychia in rabbits with streptococci from foci of infection in patients suffering from multiple onychia, an example of extreme specificity.

In the systemic or secondary focus the number of organisms is usually small, whereas in the primary foci mentioned, the number is usually large. Again, there are those who say, "Why care about infected pulpless teeth or other foci of infection since the mucous membrane of the upper respiratory tract and especially of the intestinal tract harbors millions of organisms?" It is well known that normal mucous membranes are relatively impermeable to microorganisms. In order to make the analogy more nearly correct, I would venture to suggest that the nerve supply to various segments of the intestine be cut off and that certain parts be wholly or partially ligated. Indeed, abundant evidence is already at hand in which systemic disease results from improper functioning of the intestinal tract from various causes, such as reversed peristalsis, kinks and adhesive bands, infected diverticula, and especially from an appendix whose orifice or lumen has become narrowed from scar tissue, the result of localized infection, or has become plugged by fecal concretions.

Clinical observations indicate that localized infections in certain structures, such as tonsils, teeth and sinuses, are more likely to be associated with systemic effects than those in other structures, such as the lung in bronchiectasis or the urinary tract in cystitis and pyelitis. This may be due to a difference in the kind, number, or invasive power of the bacteria in these locations or to peculiarities of the tissues harboring such foci. In general, it may be said that the harm which is prone to come from foci of infection is directly proportional to the lack of drainage to the surface. The more virulent the bacteria, the less they need a gross focus for entrance, and the lower their virulence the greater is the factor of focal infection in the production and maintenance of chronic disease. However, there is much clinical evidence indicating that foci of infection, as in tonsils, are often directly responsible for making attacks of acute infectious diseases more severe than they would otherwise be, and for increasing the incidence of complications, such as in diphtheria and scarlet fever. Foci of infection in the upper respiratory tract, as in the tonsils, may also be of epidemiological importance, as is indicated by the suddenness with which the diphtheria carrier state disappears after tonsillectomy. In fact, the question of focal infection in its broader sense is as wide in its scope and as difficult of proper application as is the practice of dentistry, medicine and surgery combined. It cannot be applied by rule of thumb any more than can the healing art. A focus of infection, that for mechanical or any other reason cannot heal or drain, that is teeming with organisms, often in mixed culture, must ever be considered not only as a favorable place of entrance but also as a good place for bacteria to maintain or acquire high and particular invasive powers. Clinical observations support these contentions, and experimental results have gone far to establish them. Thus, control experiments with cultures from the buccal mucous membrane, the surface of the tonsils and throat often proved negative, the animals usually remaining well and entirely or relatively free from lesions, whereas strains from the depth of the focus produced characteristic lesions. Moreover, direct experimental proof of this fact has been obtained in the production of chronic foci by the devitalization and infection of teeth in dogs. Strains from patients with arthritis, nephrolithiasis and ulcer of the stomach, having elective localizing power, often retained this property for many weeks and months in the periapical structures of the tooth so infected, whereas several atrobic platings sufficed to destroy it completely.

The best proof of the etiological relationship of a focus of infection to a given lesion is the production of the lesion in animals with bacteria isolated from the focus in the patient.

Through the use of special cultural methods in which due consideration was given the question of oxygen tension and the injection of animals with the freshly isolated strains, extremely characteristic localizations were obtained with Streptococcus viridans from patients with subacute bacterial endocarditis, and with streptococci isolated from the joints of patients with rheumatic fever before the idea of elective localization occurred to me. The peculiar localizations obtained were considered as being due to different species of streptococci, rather than to peculiar temporary properties of different strains of the same species. It was not until ulcer of the stomach was produced in animals during my study on the transmutation of pneumococci and streptococci with socalled laboratory strains that had attained a certain grade of virulence from successive passage through animals that the theory of elective localization took definite form. The long series of experiments in animals that have been done since by myself, my pupils and independent workers, leaves no doubt that the elective localizing power of the bacteria in foci of infection largely determines the location of the systemic lesion or diseases a person with foci of infection is likely to develop. This statement should not be taken to mean that this always occurs independently of predisposing factors, however. Exposure, trauma and fatigue of certain

structures, improper food and bad sanitation, lack of sunshine, alcoholism and other excesses and heredity, undoubtedly lower the threshold of local or general resistance and thus greatly increase the likelihood of elective localization of bacteria and other infective processes. Direct intravenous injection of bacteria which had grown in foci, such as those contained in small amounts of pus from tonsils, has often been followed by localization with the production of lesions corresponding to those in the patient. Moreover, the specific affinity was sometimes so marked that it was not always necessary to give the injections intravenously; this observation answers an objection raised regarding numbers of bacteria injected in routine work. Introduction of the bacteria in suitable dose into the peritoneal cavity, the trachea, the brain, the stomach, the rectum, or into nasal cavity by packing the nose with gauze soaked in the culture, was followed by specific localization in certain instances, especially when the more virulent strains were used, thus supporting the clinical observation that systemic disease is not always attributable to a demonstrable focus of infection.

In order to remove all doubt regarding the importance of latest foci of infection as an important factor in the production of disease, Meisser and I produced latent foci by devitalizing and infecting the teeth in dogs, closely simulating the conditions often inadvertently induced in persons by dentists. Nephritis, nephrolithiasis, ulcer of the stomach, spasms of the diaphragm and other muscles, and chorea, have been produced in this way with cultures isolated from patients with these respective diseases, and in each instance the causal relationship of the organism introduced into the teeth to the metastatic lesion, has been established by the demonstration of the organism in the lesions and focus and by the elective localizing power of the strains isolated at the end of the experimental period. During these latter experiments another important fact was noted. The bacteria in the induced latent focus of infection, besides producing the characteristic disease, appeared to exert general deleterious effects. The animals lost weight and became more susceptible to intercurrent infections, although they were kept under conditions identical with those of control animals. In other words, conditions of hygiene and diet that were adequate to maintain weight and health in normal dogs were inadequate for dogs with latent foci of infection. The harm, therefore, from improper food or sanitation may be greatly exaggerated by bacteria harbored in foci of infection, a point not yet sufficiently considered.

In my experiments still other important facts have been brought to light. Streptococci having the same specific localizing power were demonstrated in more than one focus in the same person simultaneously, and in some instances at intervals in one or more foci over a long period. These experimental results are in harmony with the common clinical observation that persons affected with a particular disease, such as iritis, ulcer of the stomach or arthritis, are prone to have recurring attacks of the same disease, which often tends to become chronic in character. In the light of these facts, the possibility that the tissues or fluids of the body afford the conditions on which the development of the peculiar localizing power of bacteria depends, must be seriously considered. The hereditary tendency observed in some of these diseases also points in this direction, as does the repeatedly made observation that a higher incidence and more marked lesions occur in the characteristic organ or tissues of animals infected with the organisms from foci at the time of acute attacks or during acute exacerbations in chronic affections, than during quiescent intervals. Moreover, well marked differences in the incidence and severity of specific lesions were noted at different seasons of the year, especially in chronic ulcer and arthritis. During the colder months when exacerbations and an increased incidence of these diseases are so common, the incidence of positive results in animals was appreciably higher than during the warmer months, when patients were relatively or entirely free from symptoms.

The fact that bacteria of the same species localize electively, depending on the degree of virulence or other acquired property, is no more remarkable than the fact that bacteria of different species tend to localize in particular organs or tissues. The loss of virulence of streptococci or other bacteria on artificial cultivation and its increase on passage through animals, are well recognized. The change in localizing power likely occurs for the same reason.

The reasons for the elective localization of bacteria are still obscure. No doubt the same principles apply that determine the localization or pharmacological action of chemicals and drugs. Indeed, my experiments in ulcer of the stomach and epidemic hiccup strongly support this hypothesis. It was found that strains of the streptococci from patients with ulcer which had elective affinity for the mucous membranes of the stomach and which produced ulcer on intravenous injection elaborated a poison or toxin within the bacterial cell and in the broth which had specific damaging effects. Injection of the washed dead bacteria and filtrates of actively growing cultures produced hemorrhage and ulcer of the stomach without inciting lesions elsewhere. Even more striking were the results following intracerebral injection of living cultures of the streptococcus from patients with epidemic hiccup, the dead bacteria, and filtrates of freshly isolated cultures. In each instance, spasms of the diaphragm or other muscles was produced. Moreover, filtrates of nasopharyngeal washings and pus from tonsils at the time of attacks sufficed to provoke spasms, whereas similarly prepared filtrates after recovery were without effect. Aside, therefore, from the specific attraction or tropism of certain cells or tissues for certain bacteria, their localization and growth in certain tissues are dependent on the production of toxins or poisons which damage those tissues specifically. The specificity of some of the strains was so marked that intravenous injection in pregnant rabbits was followed by localization and lesions similar in fetuses and mother rabbits. The view held by obstetricians that foci of infection predispose to miscarriage or to the ill health of the fetus is supported by clinical and experimental findings. Many facts indicate that diseases of the heart and vascular system may commonly be attributable to focal infection and elective localization. Thus, intra-

venous injection of a streptococcus isolated from the pus expressed from pyorrheal pockets in a patient who had had repeated attacks of muscular rheumatism and who was suffering from attacks of syncope due to a damaged His's bundle and inspired myocardial conduction besides producing lesions in skeletal muscles, produced arryhthmia of the heart, with lesions in the myocardium including the His's bundle. Marked lesions in the myocardium of animals sometimes follow the injection of streptococci freshly isolated from pulpless infected teeth and after repeated passage through animals. Haden reports similar results with strains from infected teeth of patients suffering from myocardial disease. The farreaching deleterious effects which focal infection may have even in conditions generally thought to be hereditary in origin, are indicated especially by the work of Talbot, who says, "The evidence tends to show that most congenital malformations which are the results of lack of embryonic development are due to injury to the placenta during the early weeks of pregnancy; that the injury to the placenta is due to maternal hematogenous infection of the blood vessels of the placental site, and that the source of the hematogenous infection is generally to be found in the teeth and tonsils."

The practical applications of the principles of focal infection and elective localization are fraught with many difficulties. Systemic diseases, once thoroughly established and often associated with anatomical changes that in themselves may continue to give rise to symptoms even though there are no organisms present, may continue after all evident foci are removed. The instances of cure or arrest of progress in systemic diseases by the removal of foci of infection are so numerous that search for and removal of all foci possible is indicated in almost every case of serious systemic disease, for which there is good clinical or experimental evidence of focal origin. In a given case the variations in the invasive power of the bacteria, the wide differences in natural or acquired resistance to microbic invasion in different persons and at different times, the age and sex, the history of previous attacks, the duration and character of the disease from which relief is sought, and hereditary tendencies, must all be considered in determining when and whether all or certain foci should be removed, or whether the condition is indeed of focal origin.

To arrive at a correct diagnosis and to manage focal infection properly often requires the advice of specialists in the various branches of the healing art, as well as that of a competent bacteriologist. The opportunities of the dental profession have been greatly increased through the better understanding of the problem of focal infection in general and especially of the dental area. Many problems are still unsolved but enough have been solved to prove that prevention and elimination of oral sepsis should henceforth take precedence over preservation of the teeth, which has been practised in the past, almost wholly for mechanical or cosmetic purposes. Preventive measures should begin in childhood with a view to obtaining proper development of the teeth and oral cavity. The principles underlying various procedures for the prevention and cure of infections of the gums and enveloping membranes of the roots of teeth are fairly well understood and effectively applied by many.

Infections of the dental pulp, pulpless teeth and apical abscesses are theoretically the most dangerous of the various forms of dental foci. They are usually free from symptoms and hence unsuspected. They are situated in osseous tissues which allow no expansion. They can drain only into the circulation and are exposed to pressure transmitted by the teeth during mastication. The infection remains active for years and the bacteria are not encapsulated as is usually assumed, but are found in areas of active inflammatory reaction where the formation of new bloodvessels affords drainage into the circulation or lymph stream.

The bacteriological study and the animal experiments carried out by myself, by Meisser and others working with me, by Hartzel and Hemici, by Price and especially by Haden, prove that vital teeth free from caries are usually sterile but that practically all pulpless teeth removed from patients are infected and that with the organisms isolated, usually streptococci, a wide range of lesions or the disease from which the patient is suffering may often be reproduced in animals. The infection in pulpless teeth is usually present whether or not the teeth show rarefaction in the röntgenogram. Moreover, it does not seem to make much difference whether the root canal had been properly filled or not. The idea of focal infection has often been wrongfully condemned because one or more pulpless teeth that showed rarefaction had been removed from a patient without benefit when pulpless teeth that showed no rarefaction were thought to be sterile and left untouched, or when foci elsewhere were not even considered. Again, simple extraction of infected teeth while usually, is not always, sufficient to eliminate infection in the jaw. This seems peculiarly true if teeth have been rendered pulpless artificially. In the individual cases that method of removing infected teeth should be chosen which assures elimination of the infection, which is least destructive, and which is associated with the lowest incidence of constitutional reactions manifested by fever and exacerbation of the systemic condition. Exacerbation following extraction of teeth should be regarded as experimental proof that the infection around the teeth removed has causal relationship and that in all likelihood not all of the infected tissue was eradicated during the operation.

A tooth from which the pulp has been removed or which has died from infection seems to become a place of lowered resistance to bacterial invasion. The methods generally used in root canal work are certainly not adequate to prevent subsequent infection. The wholesale devitalization of teeth and the filling of root canals, often for trivial reasons as practised in the past, considered in the light of our present knowledge, should be regarded as veritable experiments on human beings and must cease. It is greatly to be hoped that an efficient method may be found that will not only sterilize pulpless teeth and periapical tissues that have become infected, but prevent subsequent infection, especially of the periapical tissues. The fulfilment of this latter requirement seems almost unattainable. Until this has been accomplished it would seem wiser to remove teeth

that have become infected or that require extirpation of the pulp than to retain them and have them become a source of infection later. No one deplores more than I the ruthless extraction of teeth which has been practised in some instances as a result of the work on focal infection. Vital teeth free from pyorrhea should never be extracted except as it becomes necessary for restorative work. The extraction of pulpless teeth seems to me to be indicated even regardless of the appearance of the röntgenograms, in cases of serious systemic disease for which no other focus can be found. Good effects are especially prone to follow in cases in which the teeth were heavily infected and in which it is possible to reproduce the disease in animals with the bacteria isolated. The results from the use of vaccines prepared from the strain proved to be guilty are also often strikingly favorable. Since the diseases which are commonly the result of focal infection are usually due to streptococci, immunity to which is of short duration, not too much should be expected from the use of specific vaccines or serums. They cannot take the place of removal of a cause, the focus.

The removal of foci of infection, particularly if the focus is situated in tissues which may be readily spared, such as tonsils and teeth, should be practised in certain instances not only as a curative but as a preventive measure. General deleterious effects, including lowered resistance to intercurrent infection, as well as specific localization, occurred in dogs in which focal infection had been induced artificially in teeth. This may be regarded as furnishing an experimental basis for the improvement in general health so commonly observed, and for the favorable results obtained in the treatment of diseases such as diabetes, syphilis, and pulmonary tuberculosis following the elimination of foci of infection.

Extraoral Method of Stomatological Röntgenography

*A New Method of Stereoröntgenography of the Jaws and Teeth**

PROFESSOR A. CIESZYNSKI, M.D.,
Lwow, Poland

EXTRAORAL METHOD FOR JAW RÖNTGENOGRAPHY

In order to obtain röntgenograms of the jaws, along with the teeth, from the angle of the maxillary bone to the median line, the extraoral method is applied. The only technical difficulty met with here is the necessity of removing the shadow of the opposite side of the maxillary bone as well as that of the vertebral column. This difficulty is overcome by directing the chief ray under the border of the opposite maxillary bone (Fig. 1) or between the ascending ramus of the maxillary bone and the vertebral column. This can be done in a simple manner if we wish to take a röntgenogram of the skull. To indicate the direction of the chief ray we have merely to close one eye and place the other in such a position as to observe the part of the jaw we wish to appear conspicuously on the plate (Fig. 3). Then we set the focal point in the place of the eye and obtain a picture of the jaw, unconcealed by undesirable shadows.

It is more difficult, however, to discover the right direction of the centre ray in dealing with living subjects, as the skull is covered with soft parts which render the ascending ramus and the spine invisible. This difficulty disappears, however, when we indicate a horizontal section of the skull on the diagram, which is affixed to the cap on the patient's head (Figs. 4 and 5). The direction of the centre ray, the position of the plate, and the parts of the skull to appear on the exposure are all indicated by the same color on the diagram.

We distinguish three chief places on the jaw that may be all taken in one exposure: the region of the front teeth (I, oblique exposure), that of the premolars (II, oblique exposure), and that of the molars together with the ascending ramus (III, oblique exposure).

In making lateral exposures it is necessary to aim the chief ray under the border of the opposite jaw, so that the median plane of the patient's head is parallel with the plate. The central ray falls at an angle of 60° (Fig. 1).

The typical exposures are shown in Fig. 6, which should be used as follows: in the column of the first vertical line choose the most suitable exposure, showing the part of the jaw it is desired to obtain. The second and third vertical columns show how the head is turned to suit the position of the plate and the direction of the central ray. By using this diagram we obviate failure, save time as well as plates, and once the exposure is obtained, we are able to repeat it with the greatest precision.

The correct direction of the central ray may be more easily obtained by means of a triangle, of which one angle is 70° and the other 60°. The edge of the triangle was placed at the height of the open mouth. (Fig. 7.)

Extraoral technic becomes so simple when the diagrams and cap are applied that the merest laboratory assistant may perform it quite correctly by following the directions of a physician.

NEW METHODS OF STEREORÖNTGENOGRAPHY OF THE JAWS AND TEETH

The stereoröntgenography of the jaws is of use in localizing foreign bodies or missiles imbedded in the jaws, likewise unerupted impacted teeth. It helps us also to examine more exactly the shifting of fragments in jaw fracture, and to determine the lines on extraoral röntgenograms of the maxillary bone.

The technic of the stereoröntgenography of the jaws corresponds to that applied to the other organs, being based on the following principles:

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

1. The head ought to be in the same position for the second exposure as for the first.

2. The target of the x ray tube is shifted the space of the pupil of the eye, i. e., seven and one half cm., and the chief ray should be directed on the same point of the object as the first exposure.

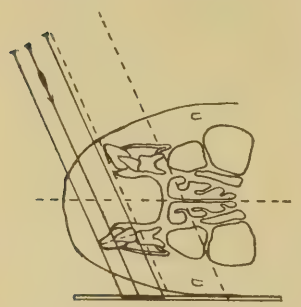

FIG. 1.—Lateral röntgenogram. The chief ray runs under the border of the opposite maxillary bone.

In practice the following rules should be observed: first, the chief ray is directed as if for a customary exposure, after which the target is shifted to the left side, half the space of the eye pupil, i. e., three and three quarters c. m., for the first exposure, and seven and one half cm. for the second, the central ray being in both instances aimed at the same point of the plate.

In order that the central ray (i. e., the ray passing through the principal part of the object, which part must appear in the röntgenogram) may be both an axial and a central ray, i. e., a ray passing through the axis as well as through the centre of the compression cylinder, the tube shield is tilted to one side to a certain angle of divergence, the degree of which depends on the distance of the target from the plate.

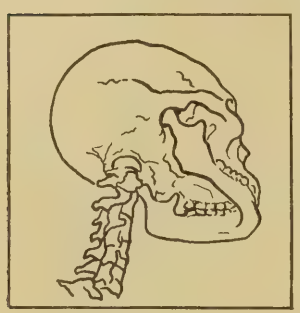

FIG. 3.—Visualization of skull at an angle allowing ray to focus on part desired.

The angle of divergence is the angle formed by the chief ray both in the first and second exposures, the chief ray being in both exposures aimed at the same point of the object (Fig. 9). This angle answers to the angle to which the tube shield is tilted, provided the movement is executed only in one direction from the normal position; should, however, the shifting motion be made to both sides, the inclination would amount to δ. If the distance between target and plate FP=fifty cm. then δ = 40°; similarly 40 cm.= 5.5°, and 30 cm.=7.5°.

FIG. 4.—Cieszynski's cap with diagram. The horizontal line on the cap is placed parallel with the Frankfort plane, the vertical lines on both sides of the cap running in a transversal plane. The median line runs through the sagittal plane. Published 1911-12.

EXTRAORAL STEREORÖNTGENOGRAPHY OF THE JAWS

The Albers Schoenberg compression cylinder, as also the Wappler tube stand (Fig. 2), is provided with an apparatus for inclining the tube. Fig. 2 shows how this apparatus is used in taking stereoröntgenograms.

Let us suppose that the distance from the target to plate FP is fifty cm.; first of all fixing screw a a is set upon the hinder part of the carriage at 4° on both sides, so that the tilting of the tube shield is automatically stopped at an angle of 4°. We now

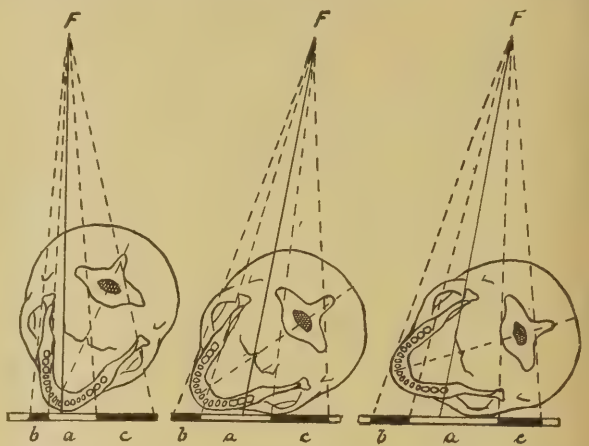

FIG. 2.—I, II, and III, oblique röntgenograms of the maxillary. a, part of the maxillary visible on the röntgenogram; b, opposite side of the maxillary bone; c, vertebral column; F, F, F, focal points of the target.

place the tube shield perpendicularly to the carriage, i. e., at point O, so that the chief ray is directed for a normal exposure. The head has also been appropriately posed and held in position. We now set the

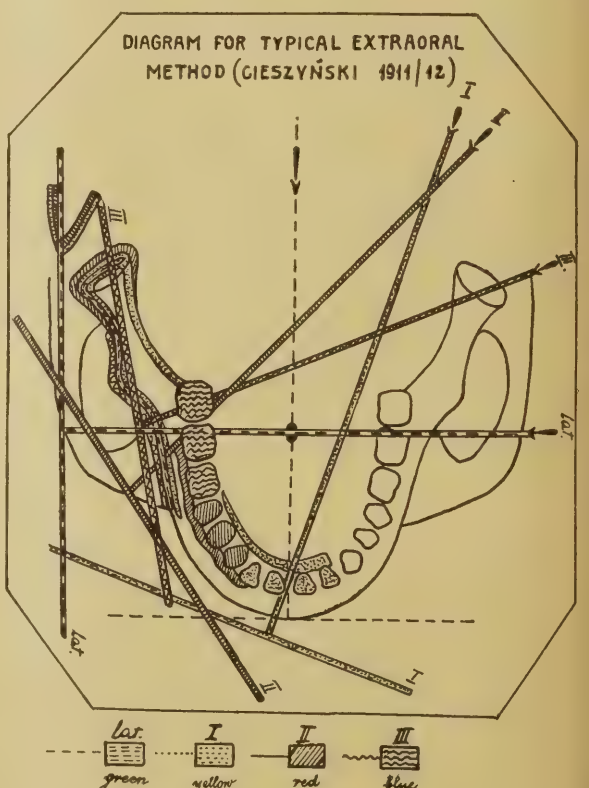

FIG. 5.—Diagram for Cieszynski's typical extraoral exposures. Three fourths normal size. Published 1911-12.

sliding bar S on point O (this sliding bar allows the tube shield to move automatically three and three quarters cm. or seven and one half cm. as desired), after which we incline the compression cylinder to the

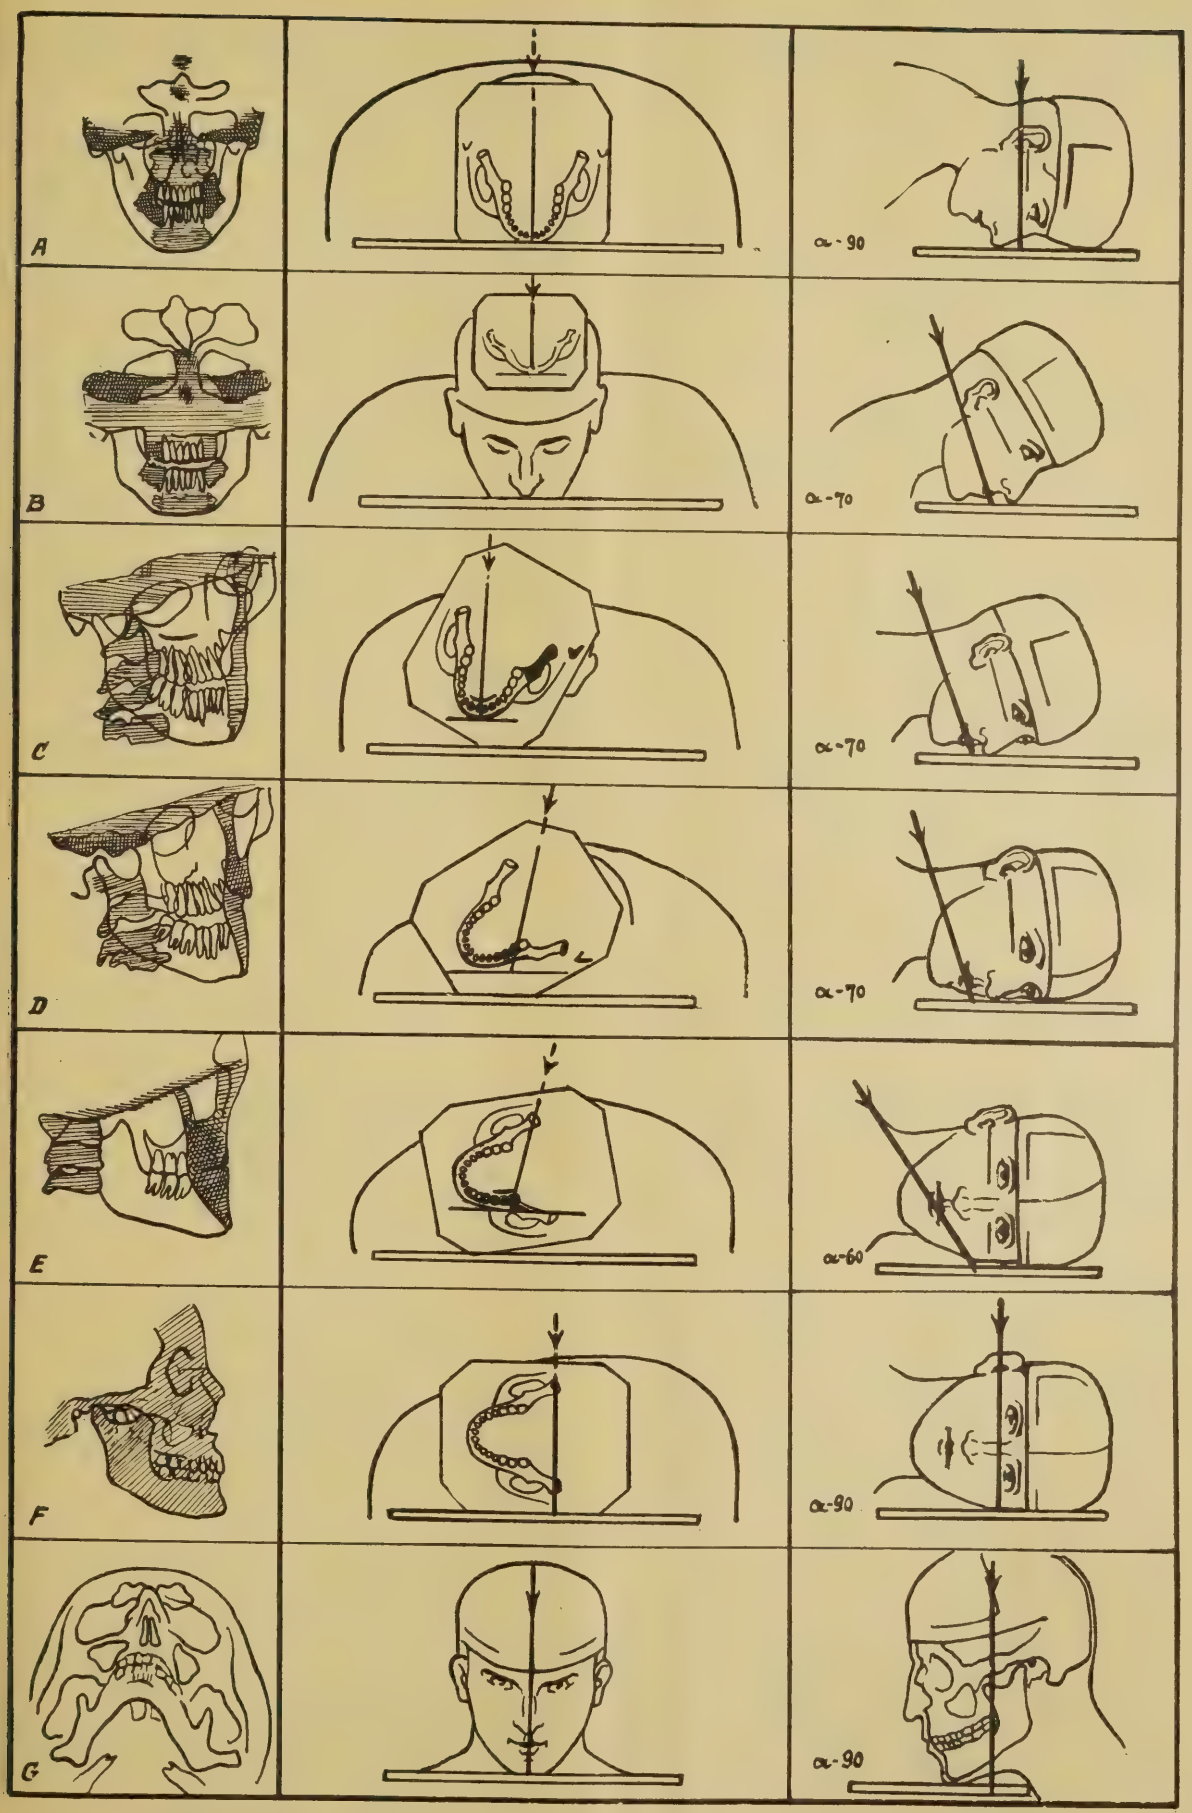

FIG. 6.—Exposures: A, occipitofrontal; B, occipitomental; C, first oblique; D, second oblique; E, third oblique; F, lateral condyloid process, angle of 50°; G, condyloid process.

left for the first exposure. After charging the plate we shift the carriage seven and one half cm. to one side for the second exposure. The distance is indicated automatically by sliding bar S.

As the indicator of the chief ray is wanting in the

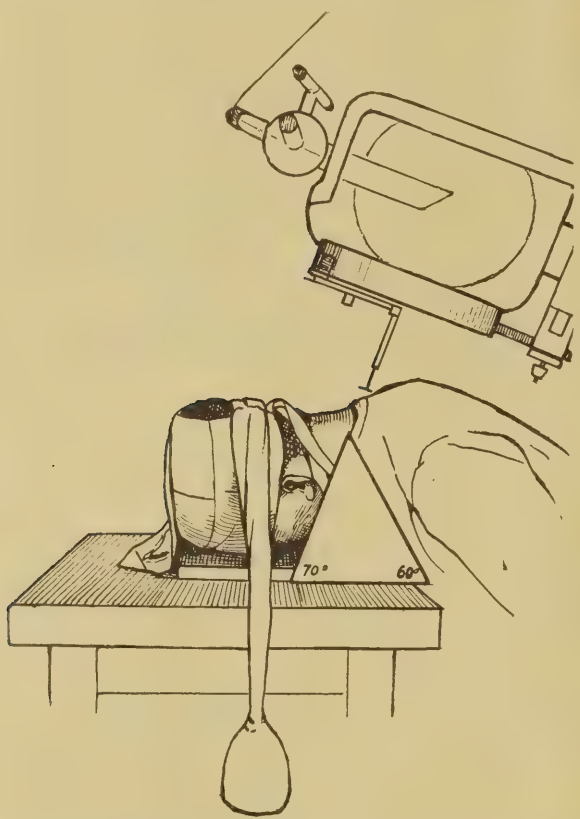

FIG. 7.—Oblique exposure I. Position of head and direction of chief ray seen from side. The indicator of the chief ray should be directed according to the edge of the triangle placed at the height of the open mouth.

tube of Wappler's stand, the deficiency may be supplied by drawing along the compression cylinder four parallel lines, extending to the axis, at intervals, as shown in Fig. 11. Line a is the directive to be followed when sighting from above, line b, when sighting from the side.

Stereoröntgenograms may also be taken by using an ordinary tube stand, in the following manner:

Method I.—On the diagram of my cap for extraoral röntgenograms, and alongside the line indicating the direction of the chief ray, we trace another line a, which forms the angle of divergence. With distance FP=fifty cm., this angle amounts to 8°, Fig. 12.

In order to take the second exposure the chief ray is directed according to the line indicated for angle δ On the diagram this line is indicated by the addition of the letter a. The object maintains the same position as in the first exposure.

Method II.—The tube stand remains in the same position for the second exposure as for the first, with this difference only that the patient's head is turned far enough to permit of the respective a line coinciding with the direction taken by the indicator of the chief ray. We assume, then, that for the obtainment of an effective röntgenogram it is immaterial whether we incline the tube shield to angle δ, or turn the patient's head to that angle, turning it towards the chief ray, which maintains the same position as in the first exposure, while the Frankfort plane of the head ought to be in the same position in relation to the plate.

The change of plates during the taking of the two exposures is done by means of the cases used for stereoradiography. As soon as exposure has taken place the photographic plates should be immediately inspected by means of Wheatson's stereoscope, or, after making a reduction, by an ordinary hand stereoscope.

INTRAORAL STEREORÖNTGENOGRAMS

In 1911 I made the first attempts at obtaining intraoral stereoröntgenograms on films in the bite position. I shifted the tube six to seven and one half cm. to one side, but without tilting it to divergence angle. I did not attach much importance to these experiments, however, and it was not till I met with a description of Ivy's handbook, of the technic of intraoral röntgenograms, that I took up the problem again, with the intention of simplifying the technic of röntgenography while using the ordinary tube stand.

Ivy executes his intraoral röntgenograms on the basis of the method applied in the case of extraoral röntgenograms, making use of Wappler's tube stand. The tube shield, however, is not shifted transversely (i. e., to the left and right side of the maxillary bone), but from the vertical. In this way we obtain such a view of the object as if the patient had been in a recumbent position, and not sitting.

My own procedure is as follows: I make a point

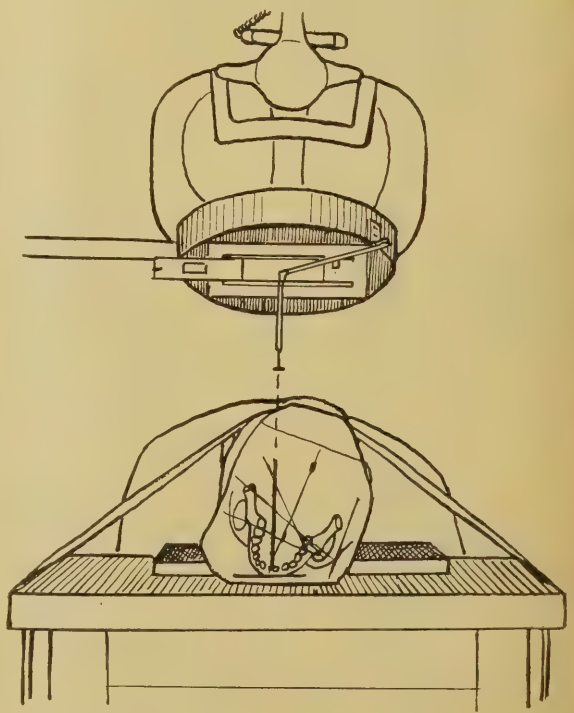

FIG. 8.—Oblique exposure. The indicator of the chief ray is placed in the direction of the line on the diagram.

of filming the intraoral stereoröntgenogram in the bite position, this being the easiest way of introducing the film between the teeth. The head remains in the same position for both exposures. By this method we obtain on our photographic plate also the lateral teeth, i. e., the molars in a mesial eccentric projec-

tion, the roots of the premolars and molars being consequently isolated. The angle of divergence is thirty to forty cm., 15° calculating the distance of the target from the film. Only the lower molars are röntgenographed on a film adhering to the alveolar process.

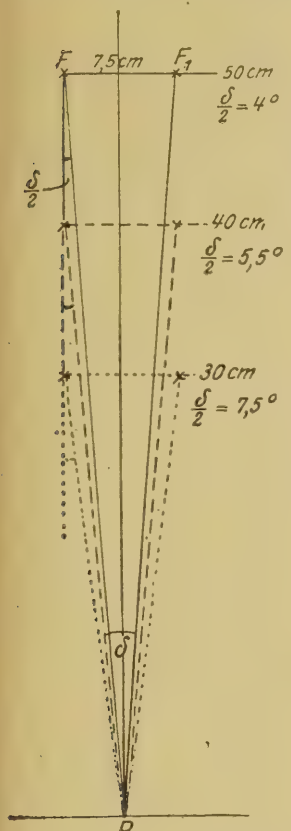

FIG. 9.—Angle of divergence, with distance between target and plate. F. D. equals 30 cm., 40 cm., and 50 cm.

The directing of the chief ray for intraoral röntgenograms is executed by following the diagram of bite plate in Fig. 13, which may easily be cut out in brass foil. Direction I and Ia are for the front teeth, while II, IIa, III and IIIa are for laterals. The plate is purposely cut to a somewhat smaller size than that of the normal dental arch, so that it may also be used for jaws of smaller dimensions.

M is a small band soldered to the obverse side of the plate; it indicates the depth to which the plate is inserted in the mouth, the plate being introduced far enough for the band to touch the exterior side of the lower teeth. The direction of the chief ray is engraven on both sides of the plate. Line F shows the course of the edge of the film, which is placed *upon* the plate when the röntgenogram is to be taken. To take the second exposure the film is taken out of the mouth together with the plate, while the head remains motionless, leaning upon the head support, after which the second film is placed in the mouth. The same apparatus is used both for the lower and the upper teeth. For röntgenograms of the lower teeth the plate is merely turned over, so that band M touches the outer side of the upper teeth, the film being placed under the plate. Two exposures are made at distance FP thirty cm., the chief ray, in the first instance, passing through line I, in the second, through line Ia. Röntgenogram II is taken either by aiming the chief ray in the direction indicated on the plate by the addition

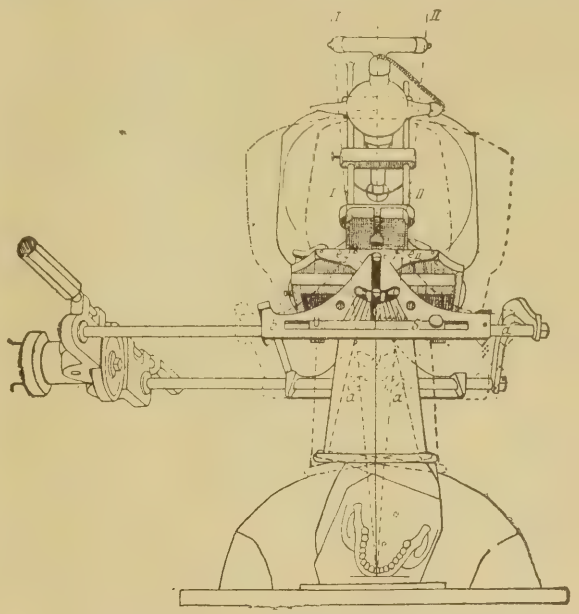

FIG. 10.—Stereoradiography of the left side of the jaws. 1, exposure taken from a certain angle by Wappler's tube stand, only the tube bracket and carriage of the stand are shown on the sketch. Carriage b on which the tube shield may be inclined from swivel point e, moves to and fro on double rails. This carriage contains an angle-meter for fixing the angle of divergence. The offrail has two fixing screws, aa, which may be set to suit the given angle of divergence. These screws prevent further inclination of the tube shield. The carriage runner nearest to us contains a slot in which the sliding bar is moved along the slot of the runner. This sliding bar permits the carriage being shifted no more than seven and one half cm., either to right or left, so that if we fix the mark of the sliding bar to point 0 on the angle meter by means of the screw, we can move the carriage only three and three quarters cm. to right or left. The fixing screws mentioned, aa, and sliding bar s, enable us therefore to shift the tube to the side and to incline it to any desired angle of divergence by one movement during the second exposure. On the patient's head is seen Cieszynski's cap with diagram. The posing of the head by means of the slit band is not shown in the sketch, Fig. 2.

of the letter a, the head remaining in the same position as in taking the first exposure, or else by turning the head round to the angle of divergence, turning the guiding line on the plate in the direction of the indicator of the chief ray, but without shifting the position of the tube stand. In turning the patient's head, however, care should be taken that the Frankfort

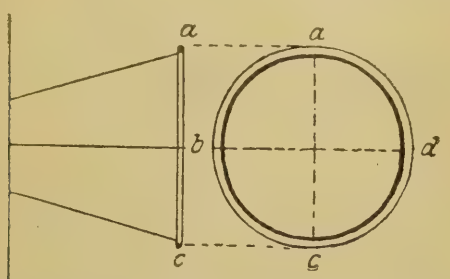

FIG. 11.—Substitute for chief ray indicator. Lines a, b, c, d, are drawn along the compression cylinder, so that the conical cylinder is divided into four even parts. The upper line, a, shows the direction in which the chief ray must be aimed if we take our bearings from above, while lines b and d are to be taken as directives if we sight from the side (Cieszynski).

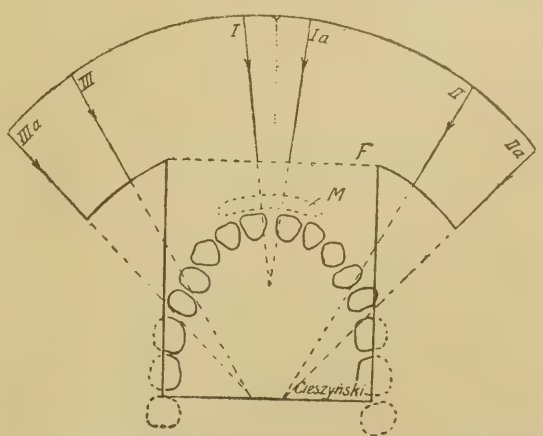

FIG. 13.—Cieszynski's diagram of plate for intraoral stereoröntgenograms (one half natural size).

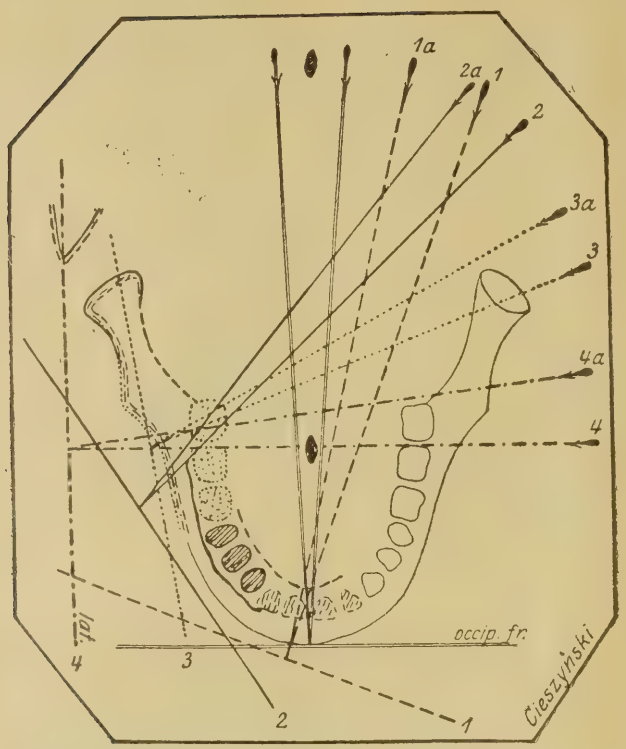

FIG. 12.—Cieszynski's diagram for directing chief ray for extraoral stereoröntgenography. On the diagram we see the position of the plate and the appropriate direction of the central ray for the various kinds of exposures, as also the angle of divergence for distance, FP, fifty c.m. The diagram becomes more lucid by coloring the various lines as follows—red, yellow, blue, remains black.

plane, traced on the face, should preserve the same position in relation to the level, and that the head support should not be moved.

The angle of inclination of the chief ray, in relation to the Frankfort plane, remains the same as in ordinary radiography, i. e., we again make use of Cieszynski's diagrams for intraoral method (4), in which the angles of inclination are given both graphically and in arithmetical figures, whether for jaws of normal build or otherwise.

The films being exposed and dried, we now place them on a glass or celluloid plate of the size of an ordinary stereoröntgenogram (nine by eighteen cm.). Then we divide the plate into two equal halves by means of a pencil line drawn through the centre of the glass, after which we mark off two points, one on each side of the dividing line, and at three to three and one half cm. from it. We now turn over the glass plate and place the röntgenograms upon it, one on each side of the aforesaid dividing line.

In looking at this röntgenogram we must imagine that we have obtained a view from the outside of the maxillary, wherefore we place the röntgenogram on the left side, on which the right side alveolar process is more extensive, that on the left side being curtailed, with overlapping teeth. The röntgenogram taken from the right side shows the converse conditions. In order to obtain regularity in distance on the röntgenograms, we first of all fix upon either the same edge of the tooth, or a filling, or any other landmark in the centre of the röntgenogram, provided that it correspond exactly; then we place them in such a manner that these guiding points shall tally with the marks made on the obverse side of the glass plate, at the same time trying to make the two pictures correspond as to position.

Having thus indicated exactly the position of films, we now affix them to the glass plate by strips of gummed paper, and having mounted them like magic lantern slides, we are able to examine them through an ordinary hand stereoscope, the most suitable being one with covered sides and dulled bottom.

The Problem of Modern Stomatological Education*

PROFESSOR J. SZABO, M.D.

Budapest, Hungary

As it is recognized today man's health depends upon the harmonious and perfect function of each of his organs and as it is universally agreed—thanks to our medical knowledge—that the pathological condition of but one organ influences the whole organism and may destroy it, there is no doubt, that only such one is enabled to treat dental diseases who is fully acquainted with the functions of each part and of each organ of the whole organism and knows the effects of dental diseases upon the surrounding tissues and upon the whole organism, that is, the physician.

The socalled dental treatment has developed—during half a century—to dental therapy, to stomatology, that is, to a medical branch. Its purpose is not only a technically perfect filling, or an inlay, or a denture, but in recognition of the fact that he is working on the living organ of the living organism, the practitioner must pay all his attention to the medical principles and must be guided by medical indications. In consequence it is not limited merely to dental treatment, but it includes the whole

*Read before the annual convention of the American Stomatological Association, April 6, 1926, at the New York Academy of Medicine.

oral cavity, its task is the conservation and the re-establishment of oral health.

It results from these statements that every physician ought to be acquainted with dental diseases, the disturbances resulting from them in the oral cavity and their influences on the whole organism, that is, that every physician, in a certain degree, should be a dental surgeon, inasmuch as he is also a surgeon and an oculist. Further, it results that the dental surgeon, the stomatologist, ought to have a complete medical education like every other specialist, that is, that he ought to be a physician.

If we ask after these statements what may be the best method, the best way, of special instruction, we must divide the problem into two groups: 1. We must inquire in what manner the practitioner may acquire dental instruction, at least in the same degree as he has acquired knowledge in other special branches. 2. We must discuss the special instruction of the dental surgeon, the stomatologist. Our suggestions comprise, 1, the general medical instruction, and 2, the problem of special instruction.

At this time my suggestions will be but statements of principles, reserving further details for a later occasion.

I. When graduating a student with the diploma of M.D., the university assumes a knowledge in every branch of medicine. He should be able to recognize various diseases and be able to treat each patient where special treatment is indicated. But in verity the facts do not correspond with this necessity, as in general one may obtain the diploma of M.D. without being able to make a correct diagnosis of periostitis, otitis media or laryngitis or to treat these conditions adequately. Today, there are many doctors of medicine without any knowledge in odontology, nor in otiatrics, rhinology or laryngology, excepting those who have acquired some knowledge by private diligence and study. For a broader medical culture, dentistry (also otiatrics, rhinology, and laryngology) should be obligatory subjects of both study and examinations so far as it accords to the general practice of a nonspecialist. That is especially indicated and urgent as regards odontology. The general practitioner must in every case possess a wide knowledge of dental diseases, of their pathology, etiology, prophylaxis, their influence upon the oral cavity and the whole organism. He must be able to recognize the diseases of the mouth, to perform tooth extractions and have some knowledge of possible complications.

I judge therefore the time will come when the different chapters of stomatology such as pathology and therapeutics of dental diseases, stomatological surgery of the mouth, oral diseases and their influence on general health, and oral symptoms in constitutional diseases, will be obligatory branches of medical study and subjects of obligatory examinations. According to these principles, the general practitioner will be enabled to recognize the connection of some internal, surgical or neurological situations with dental diseases.

I am fully aware that the introduction of obligatory dental studies into the plan of the medical curriculum is connected with many difficulties, but it is not impossible, seeing that stomatology is already in the teaching plan of some universities, in Italy for example since 1924, and in Austria since 1925, where the study and examinations in stomatology are obligatory.

II. As to the special instruction, two questions are put in the front rank: 1, preliminary education, and 2, professional education.

1. Preliminary education. Today the question in the entire world has been decided in favor of a higher preliminary education (equal to a B.A.).

The only basis of every medical specialty, also of stomatology, is medical thinking which may only be acquired by the route of being a general practitioner. Whoever is of the opinion that this is superfluous for stomatology, gives testimony that he is not aware of the demands of modern stomatology and does not know how important a knowledge of anatomy, physics, physiology, chemistry, histology, pathology, pharmacology, toxicology and bacteriology, is for the stomatologist.

Frequently it is stated that some medical branches are not of importance to the stomatologist. But likewise many branches are apparently useless for every other medical specialty, such as obstetrics and gynecology for the oculist and otologist or psychiatry for the surgeon. When regarded from this point of view the question is entirely erroneous, for as shown, general medical knowledge is the indispensable base of every special medical branch and though the specialist may not make use of it in the practice of some medical branches, he is, nevertheless enabled by them to recognize the inseparable relations in the organs of the whole organism, to understand and to appreciate them and to increase his medical judgment. And continuing this thought we may ask, for what purpose the physician should learn algebra or history.

2. Special instruction of course, can only be given in schools established for this purpose. In organizing schools of this kind two special points of view are important: There ought to be the possibility of learning this branch of medicine in its general medical relations in the same manner as surgery, otiatrics, laryngology and other subjects are taught in medical institutes; the institute must afford every opportunity for the most thorough instruction in the technical part of the branch.

It must be demanded that, besides odontography, special physiology, histology, bacteriology, general metallurgy, special physics and chemistry of the material for fillings, dental pathology and therapeutics, the therapeutics of oral and dental diseases, oral surgery should also be taught in these institutes. A division of these institutes into some departments cannot be avoided. Besides the different laboratories there are necessary: departments for radiography, conservative dentistry, oral surgery and others; furthermore, a department with sufficient beds for lying in patients.

Besides the actual work of the stomatologist's other practical remedies such as prosthetic work should be taught as perfectly as possible. The practical stomatologist should not make these appliances himself, for this is the task of the mechanical den-

tist, but he should be able to make them if necessary and be able to appreciate them and to indicate and employ them in his practice.

For attaining all these aims, the curriculum for this special branch should comprise at least two years' study.

RÉSUMÉ

1. The exercise of our special branch, as a medical branch, should be reserved for the physician in the interest of public health.

2. Every general practitioner should acquire some knowledge in this special branch.

3. For this purpose stomatology should be an obligatory subject in the curriculum of the future medical practitioner. It should be taught in a manner to enable the physician to recognize in his practice the relations of internal, neurological, surgical and other conditions to any dental disease. He should be able to appreciate them and to give, at least, first aid to dental patients.

4. The specialist should begin his special study only after having obtained the diploma of M.D.

5. The real special instruction should be given during two years, only in special university clinics in the same manner as to the surgeon, the otologist and other specialists. There must also be afforded the opportunity of learning the technical part of our special branch.

In Hungary, stomatology has occupied its place among the medical special branches. Odontology has been taught as far back as 1845, by an extraordinary professor at the medical faculty of the University in Budapest. In Hungary only the physician can practise a special branch of medicine and, among the fifty-five hundred practitioners in our country, there are eleven hundred stomatologists. After having obtained the diploma, the physician is obliged to pass one year in a reputable special clinic or hospital for special study. Only after this year in a stomatological clinic is he an authorized specialist, a stomatologist.

All this is not sufficient and cannot be regarded as a proper measure. It must be our aim, 1, that the general medical curriculum in our country should include an obligatory study of the relative special branches which ought to be taught and examined; 2, that the future stomatologist, after having obtained the diploma of M.D., be obliged to pass a final special examination after a special study of at least two years.

Stomatology in Italy*

PROFESSOR ARTURO BERETTA, M.D.

Director of the Royal Stomatological School of the Royal University of Bologna

The Italian school, not having a real dental past, nor private or social interests to guard, was entirely free to choose its own legislation founded upon the modern scientific conception of dentistry.

It maintains that dentistry is rightly a medical branch, and therefore in the sanitary and scholastic legislation must be regarded at the same level of the other medical and surgical specialties.

In fact, because of the close relations between the dental system and the body, we often notice dental disturbances giving place to general diseases and vice versa. Hence the necessity for the dentist to know and practice methods belonging to the general physician. In conformity with this, it is natural that the dentist ought to complete his medical and surgical education with the M.D. degree, and that the logical and exact denomination of dentistry ought to be stomatology.

Notwithstanding, the Italian law maintains the old name of dentistry to prevent public opinion confusing the profession of the stomatologists (M.D. graduates) and that of the odontologists (not medical graduates).

The Italian school firmly holds that in the professional life extended to the practice of every branch of the stomatological science (conservative dentistry, dental surgery, dentofacial orthopedia, prosthesis, etc.), must precede the complete medical curriculum.

This is the socalled stomatological conception of the Italian law to which are approaching other nations where the autonomist system still prevails. There are signs of it in the gradual raising of the level of the propedeutic studies in the extrauniversity schools, whose programs follow a real medical line. Everywhere the medical degree is not required, there one feels the necessity of raising the scientific curriculum of the dental studies, and in some cases one can notice the tendency to combine dentistry with medicine which could be rapidly done if there were not existing old traditions and strong interests.

The Italian school, which is today the exponent of the stomatological idea, follows with high interest and complaisance this evolution, slow but certain, and notices, in the New World, too, the signs of the ascent of dentistry through the larger horizons of stomatology: the American Stomatological Association in the United States of America and the Postgraduate Medical School of Stomatology (soon to be initiated under its auspices), are a noble, great and powerful public evidence.

And because the stomatological progress directly regards the theoretical and practical solution of problems among the most important of the social hygiene and prophylaxis, the work begun by the United States of America goes beyond the limits of the school and is beneficial to mankind.

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

Diseases of the Mouth—the Domain of Stomatology

JOSEPH COLT BLOODGOOD, M.D.
Baltimore, Md.

Food, infection, cancer.—There are three very interesting chapters which have largely to do with the oral cavity. One, its relation to food, the other, its relation as a source of infection, the third, as the original site of a cancer which, if unrecognized and left alone, leads to death.

In all three there is a greater opportunity for the prevention of the disease or its earliest recognition which will lead to a cure, than in any other region of the body, except the skin.

Diseases of oral cavity.—These include diseases of the lining of the mouth (mucous membrane) and of the teeth which embraces not only the part which we see covered with beautiful enamel, but the part that we do not see—the roots buried in their bone sockets. In the oral cavity is the tongue and above the oral cavity the socalled sinuses of the head which are lined with mucous membrane like the mouth and communicate with the two nasal cavities—the latter being separated from the mouth by the hard and soft palate. Behind this strictly oral cavity, somewhat like a short passageway between the oral cavity and the pharynx, are the fauces, between the anterior and posterior pillars of which lies the troublesome tonsil. The pharynx is usually known as the throat, and everyone speaks of a sore throat, although, as a matter of fact, the cause of the soreness is either the tonsil in the fauces or the adenoid where the nasal cavity communicates with the pharynx or in the sinuses which communicate with the nasal cavity. When we breathe through the nose or mouth the air passes to the pharynx and down past the vocal cords through the larynx, trachea, bronchi, into the air spaces of the lung. But when we swallow food the muscles lift the larynx against a shutter behind the tongue called the epiglottis, and the food slides over this into the esophagus—a buried tube passing through the chest behind the heart into the stomach.

A little knowledge of this part of the body will be helpful to all in getting some understanding how to protect one's self from diseases that originate in the oral cavity or sinuses.

Infection.—Years ago, in this country, when it was not overpopulated, one could drink water almost anywhere without getting typhoid fever. Within my own lifetime all the waters of this country have become polluted. Both the medical profession and the people were slow in realizing this danger, and it was years before they were protected by a proper water supply with its filtration and chemical disinfection, and later further protected, if they cared to, by a typhoid inoculation, one of the triumphs of the modern medical research laboratory.

Now that we have fairly well controlled the water supply and pasteurized the best milk obtainable and have protected the food from the worst contaminations, diseases due to bacteria carried by food, milk and water into our bodies through the mouth, have been largely eliminated. Having conquered one source of danger, we have been given a breathing spell to observe and learn how to attack other sources of danger. First, there are the respiratory diseases due to air infection, among which colds and influenza rank first. Then there are the infected tonsils and adenoids of children, the root abscesses of adults and the sinuses of all from infancy to old age.

The greatest danger of infection in the bone socket about the root of a tooth, buried in the tonsil or adenoid or dammed in one of the sinuses communicating with the nasal cavity, is that the focus of infection there (an abscess—collection of pus) is the source of bacteria getting into the circulation and producing a poison which ultimately causes such diseases known as rheumatism, joint troubles of all kinds, even to complete crippling (arthritis deformans), chronic diseases of the heart, arteries, kidneys, and, in fact, any organ or tissue of the body. We may call them diseases due to infection having their origin in the mouth or sinuses.

Chronic irritation.—Just as the air may carry into the body bacteria as we have long known that water, milk and food could, we are beginning to learn that chronic irritation on the skin and mucous membrane may produce a lesion which will ultimately lead to cancer. The habit of using tobacco for chewing, for snuffing and smoking has been established since the discovery of America, and this irritation of tobacco combined with ragged, dirty teeth, is the chief cause of cancer of the mouth.

Vitamines.—During the war food was selected for our soldiers chiefly on the basis of its caloric value. The importance of vitamines in the food was known before this horrible event, but it is only since the investigating minds were restored to peaceful investigation that research in regard to vitamines has progressed.

There is a disease called rickets which is entirely due to food which may be of sufficient caloric value, but insufficient in the proper vitamines. The perfection, therefore, of one's teeth begins with the proper food of one's mother and of the mother's milk and of the infant feeding that substitutes for, or follows, the mother's nursing. That infant feeding is the chief method of insuring good teeth has only been recently recognized by the medical and dental professions and has yet by no means reached the public. Without much doubt most of the cavities in teeth observed in children and younger individuals, observed before the gums begin to recede, are due to faulty feeding, the absence of vitamines.

Let us describe a concrete case in which proper vitamines control the healing processes in bone. Here is a young man who breaks the bone of his arm. The fracture is properly set and fixed, but the fracture does not heal. Then it is operated upon and a piece of bone is transplanted, and still it does not heal.

*Read before the Stomatological Joint Meeting of the First District Dental Society and the Vanderburgh County Medical Society, Evansville, Indiana, December 4, 1925. Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

The boy is apparently healthy. Then he is given for the first time food rich in the salts and in the vitamines necessary for bone healing. The foods that young children need and which are less necessary for the older people—calf's liver containing phosphorus and calcium lactate, substances necessary for forming bone; codliver oil, the juice of oranges and other fruits, green vegetables, milk and cream, because their essential vitamines are forced into the diet. Beefsteak and fried potatoes would not do, nor tea and toast. The ununited fracture healed in six weeks.

We are therefore confronted with a new point of view. There is such a great variety of foods and so many of them are so prepared and preserved that although they abound in energy atoms, they are deficient in the essential vitamines. These vitamines are as necessary for health as certain specific serums and drugs are to protect from disease or to cure it.

Next to the proper diet comes the care of the mouth, and in this there is, first, cleanliness and preservation of the teeth. This is a simple matter in young people whose mucous membrane is uninjured by tobacco and whose enamel is smooth. But as cavities develop in the teeth and as the gums recede and as pyorrhea (sometimes accompanied by pus along the gums) is introduced, and as the mucous membrane of the mouth is burned and irritated by tobacco in all forms, then the door is open for all kinds of infections due to known and unknown bacteria and to viruses that can pass through a filter. The irritants, ragged teeth and tobacco, lead to the local areas of chronic irritation in which at any moment cancer may begin.

Stomatology has a broader conception and vision than dentistry. Here is where the art and science of medicine and dentistry come together. The men and women trained in medicine and dentistry need training in this newer knowledge and need this broader conception and vision. The dentist must know more than the mechanics of his science and art. Extraction, cavity filling and bridge work are their great accomplishments, and this, with local and regional anesthesia, makes the surgical part of dentistry painless and a great art and accomplishment. But there is much more in dentistry than this. We must learn how to prevent pyorrhea and preserve the teeth by proper diet. The extraction of a tooth because it has become devitalized or destroyed by a cavity, or because of a root abscess, is a procedure of necessity and not of choice. We must look for the cause of dental root abscesses, pyorrhea, receding gums, and caries of the adult teeth. We have learned the relation of proper food to the preservation of the infant teeth, but we know very little about the preservation of the teeth of, or the cause of pyorrhea in, adults beyond keeping the teeth clean and filling the cavities as they appear.

The relation of the excessive use of tobacco to pyorrhea, receding gums and root abscess is suggestive, and there is an opportunity for an investigation here. In my opinion it is far more essential for smokers, chewers and snuffers to take better care of their teeth than for those who do not employ tobacco in any form. It is also my experience that when the adult user of tobacco begins to have pyorrhea, receding gums and dental root abscesses, it would be wiser and cheaper to stop tobacco.

There is evidently some relation of food to the preservation of the gums. The good circulation of the gums is maintained by chewing of the coarser foods, and if there is an absence of this kind of food the vitality of the gum is impaired.

CANCER

I have mentioned the relation of cancer to tobacco and ragged, dirty teeth. Some years ago in Salt Lake City I was given an opportunity to study the records of the Mormons and, although there was plenty of evidence of cancer of the breast, uterus and stomach, there was little of the lip, tongue and mouth. Apparently it is accepted as a fact that the earlier Mormons did not use tobacco.

The older and more recent literature is constantly calling attention to the fact that cancer in the primitive and barbaric races is almost an unknown disease. Yet, in the same pages we read of the common occurrence of cancer of the mouth in those primitive races who irritate the mouth by chewing betel nuts, or burn the skin over the abdomen with hot coal in winter weather. Apparently no race gets cancer of the mouth unless there is some form of irritation beyond that of the teeth. My accumulated evidence of thirty-five years, since 1890, clearly proves that cancer of the mouth with the rarest exception is only observed in men and women who use tobacco in some form and have ragged, dirty teeth. Nevertheless members of the profession and the people are constantly retorting that they know of a case of cancer of the mouth in which the teeth were good and the patient did not use tobacco. Mark Twain would answer that the exception proves the rule. My answer is that some men and women are liars.

For example, quite recently a woman had leucoplakia on the lower lip and beginning cancer. For three days she refused to admit that she used snuff or tobacco in any form. In desperation, on the third day, I said, "Madam, if your trouble is due to snuff, I can cure it; if not, I cannot." She admitted that she had used snuff for many years, and the statement was corroborated by her husband. Another patient wrote me just before she died of cancer of the mouth that she had smoked secretly for years before the cancer developed. In two cases of leucoplakia in women now under observation, in which both denied the use of tobacco in any form, one, after one year's observation, has just confessed to the use of snuff.

I now have many cases of leucoplakia in men and women which has disappeared completely after tobacco has been discontinued. In quite a number of them the leucoplakia has reappeared when the patient returned to the tobacco habit.

There is every reason to believe that many, perhaps the majority, of those who enjoy tobacco can continue to do so if they receive correct information in regard to the care of the teeth and the mouth. But when any adult who uses tobacco or snuff observes a white patch (leucoplakia) or any area of irritation in the mouth or on the tongue or lip, tobacco should be discontinued immediately until everything returns to normal, and as I have stated before, anyone who uses tobacco and observes pyorrhea, receding gums or dental root abscess, should also give up tobacco, at least temporarily. It is good protection for everyone to have clean, smooth teeth, and it is much more essential for tobacco users.

Neither the dental nor the medical profession, nor the people at large, have realized this any more than they did in the beginning the pollution of our drinking water or the filth in the milk.

THE X RAY AS A SEARCHLIGHT

When people have a toothache they usually respond at once and seek relief, and now as a rule the doctor takes an x ray. But when there is no toothache, but only a little swelling of the gum near the tooth, or of the jaw around the roots, the average patient waits until it gets bigger or painful. If an x ray is taken now it will reveal a little light area in the bone around the root or in the bone beyond it, and this little area may be anything from a root abscess to a cancer. But if the x ray is taken now and the treatment follows at once, the cancer is easily curable. Cancer and other forms of tumors which begin in the jaws around the teeth always give first a little swelling. When people are taught to take an x ray then, and the doctors learn how to treat properly the local area, no one need fear cancer or any of these tumors of the jaw. In these cases delay means increasing danger of death from cancer and increasing mutilation in all diseases because more of the jaw must be removed.

DENTAL ROOT ABSCESS AND RHEUMATISM

Many people, both within and without the professions of medicine and dentistry, do not realize that there may be one or more dental root abscesses without any sensation in the tooth itself. When any adult has a pain in a joint, or rheumatism, or suffers from indigestion, or high blood pressure, or of some trouble with the heart, x ray films of the teeth are more important than counting the pulse, looking at the tongue, or taking the temperature. There is neither time nor space to discuss in this article in greater detail the domain of stomatology.

CONCLUSIONS

The preservation of our health, the prevention of disease, the early recognition of diseases which will lead to their cure, depend upon an enlightened public. All people need correct information. At the present time we have great national educational efforts, but very little efforts in the community. Then the dental and medical professions need further education which will allow them to learn the secret of getting correct information to the people, allow them to recognize diseases in the early curable stages when treatment is simple and effectual and diagnosis is difficult. Then there is a third educational effort—the training of research workers, because there are many diseases the cause of which is still a mystery and for which as yet we have no preventive or curative treatment. If each community would try to do as much for itself as the public press is doing in bringing you correct information, progress would be more rapid.

The Radical Surgical Treatment of the Socalled Pyorrhea Alveolaris and Other Diseases of the Mouth*

PROFESSOR ROBERT NEUMANN, M.D.

Berlin, Germany

The question as to which treatment of mouth diseases would be best is now much more a matter of dispute than it ever has been before. It becomes evident from the most recent literature that surgical treatment has been generally recommended.

Surgical treatment embraces the following methods: 1, caustic treatment; 2, gingivectomy; 3, radical surgical treatment.

Those who advocate the first method are Roemer and Hille; the second: Seidel, Gottlieb, Ziesel, Nodine, Mueller (Würzburg), Mueller (Bern); and the third, at least with certain species of mouth disease: Robiczek, Bodo, Bonis, Loos, Kranz, Struck, Weski, Widman, Zentler, Roemer, Kantorowicz, Keller (Switzerland), Broberg (Sweden), Prinz (Philadelphia), Partsch (occasionally of my supplementary lessons in Breslau, Partsch, 1924), Loeffler, Dobrin, Fränkel.

The radical surgical treatment, as formulated by myself, allows for immediate and the distinct survey over the whole field of operation (Fig. 1). Furthermore, careful preparation of the flap of periosteum pituitous tunicle is necessary for the exact covering of the bone after the removal of calculus, inasmuch as it lies hidden underneath. Besides, it allows the preparation of the bone itself. It facilitates correct fitting of the pituitous tunicle on the bone, thus securing primary healing without danger of infection. The more I have treated mouth diseases with the radical surgical method, the more I have to emphasize, that radical surgical treatment with most mouth diseases is the sole way to success.

In my book (1) I have tried to draw up indicative details of therapeutics of the individual species of mouth diseases, hoping that this will stir up further interest. It comes forth from these indicative details, that I also recognize therapeutic measures, other than the radical surgical treatment with certain species of mouth diseases; for instance, with a supraalveolar pocket, horizontalis supraalveolaris, i. e., which I am recognizing as being useful!

SUCCESSFUL OPERATIVE METHOD

I present the following claims to a successful operative method:

1. Immediate distinct survey over the entire field of operation. Fig. 1.
2. Complete removal of concretions on the roots.
3. Complete removal of granulation tissue interwoven by epithelial ropes and hidden in the niches and inlets of the bone.

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

4. Complete removal of all pathological bone structure (transformation of vertical atrophy into a horizontal one).
5. Removal of inlets and niches of bones going underneath one another (pyorrhea intraalveolaris and cavernosa).
6. Removal of gum pockets by carrying off pituitous tunicle up to the healthy bone structure.
7. Transformation of vertical atrophy into horizontal atrophy. It is well known that healing is much more favorable in horizontal atrophy. (Weski.)
8. Covering of healthy bone with healthy pituitous tunicle in order to obtain the ideal condition of total atrophy.

The *British Dental Journal* (2), in a report of my book, made the following statement: "What most readers like to know is not, whether operative measures have immediately been successful—one may easily suppose it, for otherwise operation would have been given up—but the final success three, four, five or several years later." As I shall show later on, I have proved the procedure to have been lastingly successful three, four, five years after the operation by giving evidence to many a fellow surgeon of foreign countries as well as of my own.

The only condition for lasting success or better success on long sight and therefore for statistics of useful cases is to consider only those cases as satistical material concerning which all requirements I have pointed out as being indispensable for lasting success have been entirely fulfilled. The fact that after radical surgical treatment relapses have been traced does not refute, that under observation of the following conditions this operative method will be a useful one, if the following requirements have been met:

a. The right indication has been stated.
b. The right operative technic is used.
c. One succeeded in entirely removing all concretions, particularly at the molars at the bifurcation of the roots, in spite of putting up the folds.
d. Cases remained under careful observation.
e. Careful hygiene of mouth prevents the coming forth of new exogenous exciting causes.
f. First of all each endogenous and exogenous contributory cause is removed in due time.

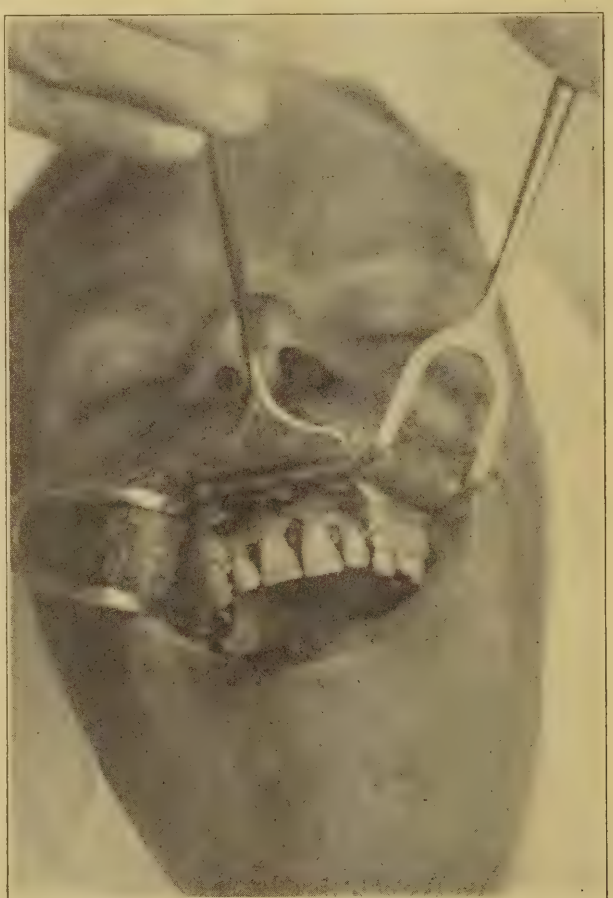

FIG. 1.—Showing the first step in a successful operation, namely, immediate distinct survey over the entire field of operation.

Operations executed by the most expert and skilful surgical operator may apear to be in a deplorable condition, if the respective patient, as it most recently happened in my own practice, is not examined for some years. And if again, in consequence of the same causes, for instance of calculus accumulation; the same disease has developed, which before the operation was the real cause of the sickness.

The cosmetic aspect, for instance, has been cited as a counter indication for this operative method. Sachs, for cosmetic reasons, does not remove the papilla. However, all authors require the removal of gum pockets. Kantorowicz states in his book which has just been published (3): "Modern paradentitial therapeutics culminate in the surgical removal of the pocket. Surgical therapeutics is divided, according to whether it is a question of gum or bone pockets, into two methods, the removal of gum and the putting up of the gum folds with removal of bone.

Roemer, too, (4) calls for removal of the pockets either by radical surgical treatment or by the destruction of deepened gum pockets by means of thermocaustic, used by him over a period of twenty-six years. He then continues:

"The operation according to Neumann is at all events justified and has its advantages in all those cases where it is a question of the following affections, a, deepened intraalveolar pocket (Weski), b, deepened intraalveolar pocket, and undermining caverns (Weski)."

Gottlieb, too, requires removal of the pockets in saying: "Nobody will ever have seen pyorrhea alveolaris (properly spoken in the real sense of the word) without pocket. It is selfevident that we have to draw the conclusion from this distinct characteristic."

Therefore, if there are cysts, tumors in the gum, the pituitous tunicle forming the boils, then the pockets are to be removed. The respective parts of gum are opened by means of hooked chisels, forcibly separated from one another in interproximate spaces, likewise shoved off and removed by curved scissors, knife or cautery. Regarding operation on front teeth, one at first may *try* for cosmetic purposes the scratching out of abscesses in the gums (hook towards the gums). In the event of this also being useless—Gottlieb continues—any further re-

gard to the beauty represents an inconsideration towards the patient himself!

REMOVAL OF BONE

Gottlieb considers the removal of the bone, that is to say the removal of all the bone pathology or

FIG. 2.—A case of cystic abscess of upper jaw, which was opened lingually and palatinally.

rather bone pockets or sockets, just in the same degree as myself and all other above mentioned authors. On the other hand, I advocate it on the basis of clinical experience, Gottlieb takes it as damaging the patient and denotes "any far reaching surgical encroachment" as being needless, and the removal of bone as a polynomial mistake of art. Apart from other points, he refers to the fact that in America one pretends having traced regeneration of the periosteum.

A report published in 1924 about the work of Professor Hermann Prinz, D.D.S., (Philadelphia) shows, that in America he is of a different opinion. Among other points, one reads as follows: "The treatment, first of all, has to consist of regulating the chewing pressure and of removal of calculus. Medication is only symptomatic, lacteal acid treatment is wrong. The solely successful method appears to be the radical surgical methods, such as have operated on cases in all stages. Patients whom Nodine, Ziesel, Zentler, Black and Widman (1911)," which means that here, too, the removal of bones is required.

Gottlieb has not yet anywhere proved röntgenologically or clinically that the principles up to the date outlined here are all recognized hypotheses. However, I can prove that my clinical observations are absolutely right, and I have done so by means of the abundant controllable material at my disposal, which I have submitted to many well-known fellow-surgeons both abroad and in my own country. I have operated on cases in all stages. Patients whom I have operated upon one, two, three, four and five years ago (with whom sometimes I have performed up to six operations in the mouth) were introduced by me to the students of a course in March, 1924, in the Deutsche Zahnaerzte-Haus and also to the members of the American Stomatological Educational Committee in July, 1925, during their stay in Berlin.

I present herewith photographs of two patients operated upon by me. The patient shown in Fig. 2 had a serious cystic abscess on the upper jaw, upon which I operated in February, 1921. It was opened lingually and palatinally. This patient has remained up to the present without any relapse. The photograph was taken in October, 1925. Constitutional attacks of illness could not be traced. Fig. 3 shows a patient I operated on in the Academic Supplementary Institute of the Reichsverband in 1924. I operated on the lower jaw before the American Stomatological Educational Committee in July, 1925. This photograph was taken in October, 1925. All illustrations are taken from my atlas, *Die Radikal Chirurgische Behandlung der Paradentose,* which will presently be published.

The Present Educational Status of Stomatology in Italy*

PROFESSOR G. COEN-CAGLI M.D.

Rome, Italy

Stomatology in Italy today is a fully recognized specialty of medicine. It was due to the combined efforts of the Italian medical profession and the Italian Stomatological Federation that Italy is proud to be one among the nations in Europe where the care of the mouth and teeth is considered and officially recognized to be equal in importance to the care of the eye, ear, nose, throat or any other part of the human body. Not only has Italy recognized stomatology to be educationally on an equal plane with other medical specialties, but stomatology has received full recognition of its importance and has been given a prominent place in the public health program. The Department of Health of the municipality of Rome provides for the care of children's mouths as it does for the prevention of tuberculosis.

The American physician and dentist has not had an opportunity to know the struggle which the Italian stomatologists have had to undergo to obtain a place for dentistry among the medical specialties in Italy. The development of the educational system for dentists in our country has been different from that of America and has proceeeded in a different direction. Prior to 1890 dentistry was practised by men who received minor diplomas, which were granted by various institutions of the States of Italy at the time when Italy was not as yet united in a kingdom. On April 14, 1890, the Boselli decree made the possession of a degree in medicine and surgery compulsory for the practice of dentistry for the first time.

It may be said, however, that Italy has always upheld the stomatological standard of education. Those who were practising prior to the introduction of the 1890 decree were permitted to continue to practise with the provision that they pass a special examination. The Boselli decree did not become law until 1912, with the concurrence in opinion of both branches of the legislature. At this time, Italy did not have good dental schools and those physicians who wished to specialize in stomatology had to go abroad, either to England or to America, to study dentistry. At the present time, we have two up to date stomatological schools in Italy, those of the Royal University of Milan and of the Royal University of Bologna.

Unfortunately, the law of 1890 was not completely and satisfactorily formulated, as it did not provide officially for the requirement of instruction in stomatology for all graduates in medicine. In the last few years, several radical changes have taken place in the educational system for dentists in Italy which you are probably familiar with.

The preliminary education for matriculation in the medical faculty consists of five years in the gymnasium, which corresponds to the high school in America, and three years lyceum, corresponding to college work. The university course in medicine and surgery comprises six years of study in a medical school. After passing the examination, the title of doctor of medicine and surgery is conferred. The title Dr. does not entitle the holder to practise medicine. A State examination must be passed in order to secure a license to practise. A duly graduated and licensed physician may practise medicine and all its specialties, this includes stomatology and restorations (prosthesis), even though he holds no other degrees.

The freedom to practise the medical specialties by M.D. graduates without special training in these specialties allowed physicians to practise dentistry without special training. The 1890 decree made no restrictions limiting the practice of stomatology to M.D. graduates with special training in dentistry. This loose construction of the 1890 decree afforded an opportunity in 1923 to effect a temporary change in the educational standard for the practice of stomatology requiring two years of training in dentistry. In Rome a small, but influential group of autonomists, among whom were some holding the M.D. degree, under the leadership of Professor Angelo Chiavaro, demanded a doctorate in dentistry, independent of medicine and surgery, somewhat after the type of the American D.D.S. "They wanted the medical student after his fourth year to relinquish his studies and join the school of dentistry and dental mechanics which was to be established in Rome, and after a curriculum of two years to pass an examination which would confer on him a doctorate in dentistry and dental prosthesis. These ideas found sympathy from the Minister of Public Instruction in Signor Mussolini's cabinet, who, owing to the full powers conceded by Parliament, secured at the end of 1923 the approval of the Council of Ministers for a decree establishing a national school of dentistry and dental mechanics in Rome; this meant the institution of a degree in these subjects at the end of the prescribed course of study and the passing of a special examination."

The 1923 decree aroused violent opposition, as medical men had pronounced in favor of a compulsory degree in medicine and surgery for dentists. Professor A. Murri, one of the leading Italian clinicians, said on that occasion: "It is logical and useful that dentistry finally enters to be a part of medicine, as all other studies of the human body."

The 1923 decree also did not restrict the M.D. graduates from the practice of stomatology without special training. In this respect the 1923 law did not improve the status of the practice of dentistry any more than the 1890 law. The only improvement that took place with the introduction of the 1923 law was that it required a two years' course in dentistry as compared with a one year course in dentistry prior to that date for those who specialized in stomatology. On the other hand, the 1923 law shortened the course in medicine from six years to four years and abrogated the M.D. degree. The

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

sentiment of our American confreres on that occasion is best told by their communications received by us on that occasion: Dr. Edward H. Angle says: "I heartily agree with you that it would be a mistake to abolish the degree of M.D. as a requirement for the practice of dentistry in your country. For your country now to abolish the degree would, I am sure, be a step backward which would have to be regained through more trouble later on." And Dr. Eugene S. Talbot: "I am surprised that such intelligent medical men should decide on such a retrograde step as to return to a purely dental college teaching. . . . Let us hope that Italy will not take a backward step in these progressive and enlightened times." Dr. Frederick B. Noyes: "It would seem to me that it would undoubtedly be a step backward to give up the requirement of the M.D. degree for the practice of dentistry in Italy."

FIG. 1.—Parchment of the Seventeenth Century presented to the American Stomatological Association by the Italian Stomatological Federation, in Rome, June, 1925.

The attempt to abrogate the 1890 law requiring the M.D. degree of all who practice dentistry failed. The Italian stomatologists favored the requirement of two years of specialization in dentistry and have retained that part of the 1923 law demanding this standard, but the Italian stomatologists were opposed to the breaking down of the requirement of the M.D. degree as a preliminary requirement for the study of dentistry. In 1921 attempts were made to break down the 1890 law and in 1922 the Italian stomatologists have finally succeeded in signing an agreement with Professor Chiavaro that he respect and make every effort to have respected the old law, with the only change, that of the two year course of dental studies for those who have obtained their M.D. degree who wish to practice stomatology. On that occasion we received a communication from Dr. Talbot (1) stating the following: "You do not know how pleased I was to get your letter this morning and to learn that our dear friend, Professor Chiavaro, has abandoned his purpose to provoke a law which abolishes the degree of medicine for the practice of dentistry. He is too well educated and too good a man to take a backward step at this time in the progress of our profession."

These trials to establish the autonomy of dentistry aroused the opposition of the medical profession who demanded the enforcement of the 1890 law without reservations. The Mussolini Cabinet rescinded the 1923 dental decree and substituted a new Royal decree of October 16, 1924 (No. 1755), which became law in December 12, 1925, through the action of the Chamber of Deputies. The law affects both the educational requirement for the study of stomatology of the medical student as well as of the stomatologist. "The new decree stiffens the statute of March 31, 1912, since it not only requires all dentists to be previously qualified in medicine and surgery, but enjoins upon all future medical practitioners the undergoing of a practical test in dentistry and mechanics to enable them to practise the art of medicine. It is not that the medical graduates of the universities, to which the new statute allows freedom in regulating their special studies, will all be finished dentists, but they will at least know enough to guide them in investigating each case and adopting proper treatment, especially in rural districts where there is no expert dentist."

With regard to those M.D. graduates, who in the past wanted to specialize in dentistry, but who are not required to follow a compulsory course in dentistry, we find that they are now obliged, in conformity with the law of December 31, 1923 (No. 2909), to take a two year course in the state stomatological schools, one of which is located in Milan and the other in Bologna.

It will be noticed that there are no autonomous schools for the teaching of dentistry in Italy for those who have not obtained the M.D. degree. The stomatological schools graduate about one hundred students annually. The Italian Stomatological Federation represents stomatology in Italy and is composed of medically qualified specialists. Dental mechanics are permitted to practise dentistry in the laboratory, but not on patients. There are mechanical dentists, those who have no M.D. degree, who are permitted to practice on patients; these men, however, obtained their diplomas before it was obligatory to have a diploma in medicine and surgery (1890). Others who were in dental practice for some time were permitted to continue to practise by special legislative enactments as a matter of expediency.

In Italy the future medical practitioner will have a knowledge of the fundamentals of dental science, as he has of ophthalmology and dermatology. For dentists in the future—i. e., medical specialists in dentistry and prosthesis—the general university reform actuated by Gentile efficiently provides in the same way as it does for all other specialists. This measure enjoined that no one can arrogate to himself the title of "specialist" in any branch of medicine without having acquired the relative diploma granted by each university.

CONCLUSION

Italy's triumph in the establishment of a high educational standard for the practice of stomatology as a fully recognized specialty of medicine is in a great measure due, not only to the cooperation of the Italian medical profession but also to our American confrères. We have expressed our appreciation of our indebtedness to the American Stomatological Association by presenting them with a parchment of the seventeenth century, which was publicly presented at the reception of the American Stomatological Educational Committee in Rome in June, 1925. (Fig. 1.)

The medical profession as well as the public has reaped benefits from the high standards of medical education in Italy at the present time. Those who wish to practice any medical specialty must pass a special examination which will be proof of a real knowledge of the specialty they intend to practise; the public will, in this way, receive the services of fully qualified specialists.

Lungo Tevere Mellini, 17.

Hygienic Dentistry—Is Dentistry to Become a Specialty of Medicine?*

GEORGE REESE SATTERLEE, M.A., M.D.

New York

The question is one that must be squarely met and decided on as to its merits. Let us study it from all angles. The principal argument from the medical viewpoint is that dentistry is the only specialty devoted to the treatment of the human body that, as a profession, is independent of medicine.

Is this situation the best for the protection of public health? Is it desirable that the dental profession shall be merged with medicine and become one of its specialties? Harmful politics should first be eliminated from both professions. Too often in the medical profession the patient has been crushed by the hydra of politics. Specialization of too fine a degree has also ruined many a patient as well as physician. Focussing on one part of the body to the exclusion of the whole is always pernicious, and can account for numerous mistakes. The body should therefore be regarded as a whole. Unfortunately the highly trained specialist is frequently unable to generalize and should not feel disgraced at calling in a consultant. This is not an argument, but an axiom.

One of the arguments from the dental viewpoint is that dentistry is not a specialty of medicine, except in that it contributes toward mastication and cosmetic effect. In other words a very large percentage of dentists do not accept the term "medical dentistry." From the mechanical point of view this argument might be accepted. A mechanic of the human body is a necessity, but if developed to the nth degree has limitations, otherwise he may become a dangerous man. This condition has its parallel in nearly all our medical specialties, notably in orthopedic surgery. The relationship between medical dentistry and mechanical dentistry has come to the foreground during the past five years. I refer to mechanical dentistry such as caps, crowns, root canal therapy and the devitalization of teeth; in fact, any kind of dental work which may obscure or wall in infection. One can quote numerous reports on this subject from physicians and dentists, but mostly from the former. Cotton, Price, Upson, Satterlee, Draper and others have demonstrated the results of bad dental work. There is now fortunately no real argument for the necessity of the removal of teeth which show definite abscesses, but the argument still hangs on the devitalized tooth. Education in radiographic interpretation is deficient and should be compulsory as the x ray has been our most valuable aid in the detection of infection. Alveolar necrosis is not generally recognized but can be detected by the x ray. This condition is responsible for a large amount of constitutional inferiority in the experience of many of the medical profession. The study of radiographic evidence need not be confined to the specialist but should be included in the dental and medical curricula as part of the education of both the dentist and the physician.

This leads to another reason why dentistry should

*Read before the American Stomatological Association at New York City on February 10, 1926. Aided by a grant from the Andrew Todd McClintock Memorial. Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

be a specialty of medicine. Close association would lead to cooperation. If the dentist understood the physician's viewpoint there would be no need of argument except as to minor details. These details need not concern us any more than the individual methods of the rhinologist, otologist, dermatologist or other specialists concern the family physician or internist. The general principles of surgical care of infection should belong to all branches of medicine, including dentistry. Public opinion usually decides a question and would soon condemn a surgeon who did not open an abscess, or continually sealed in an infected area. We should not wait for public opinion, but anticipate it. In this day of intellectual awakening we should obey the laws of Pasteur which once were despised and are now universally followed.

Why should there be friction and lack of cooperation between dentists and physicians? The reason is explained by the fact that dentists become so highly specialized that they fail to see the disastrous results of sealed infection in practice based on mechanistic theory. If dentists had had the same medical education as medical specialists the fault might be corrected. The dentist fears that the years of education would be prolonged. This is more of a phobia than a real drawback for our educational system has undergone a change for the better during the last quarter of a century! Why should dentistry not share in the advance which has proved to be of such value to both doctor and patient? The dentists argue that their profession has advanced equally and can progress by itself. An answer to this, medicine stands ready to offer to dentistry all that science has bequeathed to her. This will surely give a broadening spirit to the dental profession and an opportunity to study and discuss the local dental problem with special reference to the public health.

Many a dentist would like the moral support of a physician when the patient insists on saving a condemned tooth. The fault here lies with the patient. The answer is education of the patient, the dentist and the physician. In order to accomplish this education of dentists and physicians should be uniform to the separating point of the specialties. While dental schools have attempted to raise the standard of dental education they have overlooked two important elements in their proposed reforms, namely, 1. The need of training in a basic medical course. 2. That specialization should follow the basic course. The dental plans now proposed are altogether beyond the point of practicability. For example, one dental college proposes seven years for the dental degree. Other dental educators advocate a six years combined medicodental course, after which it is proposed to confer a doctor's degree in dental medicine. There is an indication that in the near future dental educators will realize the value of placing dental training on the same plane with other medical specialties.

For the benefit of our people we must educate our next generation of dentists to diagnose and prevent mouth infection. Medical dentistry or stomatology as distinct from mechanical dentistry, is established in Europe on a medical basis. This basis is now advocated by the American Stomatological Association. Oral surgery is recognized as belonging to general surgery and for its efficient practice the M.D. degree is advocated. In the treatment of the nonsurgical diseases of the mouth, dentists and physicians admit that a medical training is of great benefit to the practicing dentist. When we refer to mechanical dentistry the question arises, is it necessary that the dentist be medically trained? The answer is affirmative. In order that the dentist may render dental service devoid of root sepsis and general mouth sepsis it is necessary to be familiar with focal infection. A bridge constructed on infected teeth, even if they do not give immediate and apparent symptoms of infection, should be condemned. The dental mechanic who makes the bridges on the models need not have the same training as the stomatologist for he does not deal with the vital tissues.

In conclusion, the following case histories are cited to illustrate the disastrous results of the errors of lack of medical training in the dentist:

Case I.—No. 3746. Male, aged fifty years. Chief complaint, loss of weight and malaise. Patient had always been healthy, had had excellent dental work done which had been properly followed up by radiographic studies. For the past six months he had been depressed, physically tired, slept poorly, ground his teeth and groaned during sleep. He was pale and anemic and had lost ten pounds. Physical examination showed nothing abnormal except a mild grade of anemia. Dental examination showed minute areas of retained root fragments and some necrosis in the area of a former molar extraction. There was also evidence of beginning apical infection. On consultation with his dentist curetting of the molar region in question was done and the result was immediate restoration to health with regain of ten pounds. The patient had had previous medical advice to take a year's vacation. Following the operation the vacation was unnecessary and his health has been excellent for the past five years. This is one of the examples where dental infection alone could be held responsible for the physical disturbances in a patient.

Case II.—No. 3767. Male, aged thirty-one. Never robust and subject to *petit mal* seizures for several years. Tonsils and adenoids removed at thirteen. In 1910 had bronchopneumonia, followed by constipation. Three severe migraine attacks every year for fifteen years, this was especially marked in 1910 which was his bad year. Abdominal distress, indigestion with marked hyperacidity and urticaria. Weak eyes. His chief complaint was corneal ulcers since 1913. These ulcers had been recurrent, becoming more and more frequent, necessitating constant local treatment. Wassermann negative. Examination in 1920 showed patient decidedly subnormal with enteroptosis and splashing in abdomen. Typical gastrointestinal invalid. Corneal ulcers with superficial keratitis. Blood chemistry and gastric analysis normal. Fetid, constipated stools high bacterial content. Cultures gave Streptococcus fecalis and Bacillus coli from which a vaccine was made. At this time dental examination was not thorough and there was no knowledge of badly infected teeth. Treatment along the lines of diet and vaccines for immunity was moderately successful for two years. Examination of teeth in April, 1922, showed twelve badly infected teeth with osteomyelitis of superior maxilla on both sides and chronic left maxillary sinusitis. After six months' delay infected teeth on one side were removed and the bones and antrum scraped. The bone

necrosis was extensive. The patient had been in good condition until recently when he had a slight return of the corneal ulcer. During May, 1923, the patient was advised to have the remaining areas of infection cleaned up. The epileptic seizures have been arrested and the patient has gained twenty pounds.

During October, 1923, the remaining areas of infection were removed, gradual improvement in health resulted until at the present time (January, 1926) the cornea was clear, the bowels regular, the strength excellent with no more epileptic seizures. The course of this case demonstrates that the physical condition would not have cleared up without the removal of dental infection and bone necrosis.

The Food Education Society of England*

CHARLES E. HECHT, M.A., M.B.E.
London, England

The Food Education Society was founded as far back as 1908 under the title of National Food Reform Association, assuming its present name upon incorporation in 1919. Its objects are thus set out in the memorandum of association dated May 9th of the latter year:

1. To promote the physical, intellectual and moral welfare of the people of the United Kingdom, its dominions, colonies and dependencies, especially in relation to diet and hygiene.

2. To promote economy, both public and private, especially in relation to diet and hygiene.

3. To take any steps calculated to promote the stated objects of the association, and in particular to do all or any of the following things for the purpose of attaining these objects, viz.:

a. To initiate and carry out inquiries concerning matters of diet and hygiene and public and private economy and to issue reports or other publications.

b. To collect, consider and disseminate information bearing on the stated objects.

c. To print, publish, issue and circulate a journal or other periodicals, books, leaflets, or other literary matter, or to aid in such printing, publishing, issuing and circulating.

d. To institute lectures and demonstrations and to hold or take part in meetings, exhibitions, conferences and congresses calculated to promote the objects of the association.

e. To found research scholarships, lectureships and like educational enterprises and to train lecturers and demonstrators and others and grant diplomas and certificates and employ individuals for the furtherance of the work of the association at such salaries as the association may resolve upon, provided always that every such diploma or certificate shall contain on its face a statement to the effect that it is not issued under, in pursuance, or by virtue of any statutory or government sanction or authority, but by the authority of the association only.

f. To furnish information to Parliament, Royal Commissions, County Councils, Boards of Guardians, sanitary and other public bodies, municipal and other corporations, educational and other committees, and to private individuals, and to aid in the enforcement of the law affecting or relating to diet and hygiene.

g. To promote and cooperate with others in promoting administrative and legislative reforms in matters relating to or affecting diet and hygiene.

h. To cooperate or to become associated with any other organization, institution, or society whose objects are similar to those of the association which by their constitution prohibit the distribution of their income and assets among their members to an extent at least as great as is imposed on this association by clause four herewith.

i. To establish branches of the association in the United Kingdom or elsewhere and to delegate to them any powers as shall from time to time be considered desirable by the association.

From the outset prominence has been given to the subject of oral hygiene. The usefulness of its propaganda was early recognized by an invitation to contribute an exhibit to the illfated International Dental Congress held in London during the first few days of the great war. At children's welfare exhibitions before the outbreak of hostilities, as at national economy exhibitions throughout the country during the years 1915-18, models of children's teeth were shown and explained and much literature sold. Talks were also given at the last mentioned exhibitions to thousands of school children and to adults. Publications such as *Aids to Fitness,* now in its twenty-third thousand, *Why Worry About Sugar? Eat Victory Bread,* together with a series entitled *Facts for Patriots* (dealing, inter alia, with bread, sugar, sweets, fruit, vegetables, salads, milk, cocoa and chocolate) as well as a steady flow of letters to the press, have all played a part.

The teeth figured conspicuously at the Guildhall School Conferences of 1912 and 1913. *Rearing an Imperial Race,* in which the proceedings of the second conference are included, with much besides, has found favor in America and was reviewed in the *American Journal of Public Health.* Writing of this volume and of its predecessor, *Our Children's Health at Home and at School,* Dr. C. F. Langworthy, Chief United States Nutrition Investigations, said: "I have recently been examining them with much interest."

With the Manchester Conference on the Prevention of Diseases of the Teeth, 1920, the climax of the campaign was reached. *The Gateway to Health,* published a year later and containing a full report of the papers and discussions extending over two and a half days, with a large amount of additional matter, has found equal favor among leaders of the medical and dental professions. It is likewise being

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

studied by social workers and the general public. Many orders have been received from the United States. It is particularly gratifying to learn that it is regarded by the editor of the *Review of Clinical Stomatology* as "a valuable contribution to the literature on public stomatology." The society sent a representative, in the person of its vice-chairman, Sir Harry Baldwin, to the conference convened on January 16, 1925, by the Dental Board of the United Kingdom. The chairman of the board (The Rt. Hon. F. D. Acland, P.C.) suggested that those present "would be glad to hear more of the Manchester Conference." The honorary secretary was subsequently invited to serve on the advisory committee appointed by the Dental Health Propaganda Committee and received the thanks of the board for his services upon this and two sub committees.

Further details of the educational work done by the society are to be found in a paper read to the School Dentist Society in December, 1919, and again at the Manchester conference.

For some years past the society has had a stall at the exhibitions in connection with the annual meetings of the British Medical and British Dental Associations, as at the London Medical Exhibition, Nursing Exhibition, London and provincial, and at the Conference of Educational Associations. At the latter papers have been contributed on such subjects as Diet as an Essential Factor in Education, School Children's Diet by Dr. Harry Campbell, and The Diet of Educationists. A large and growing amount of propaganda is accomplished on these occasions.

In her cookery demonstrations The Pudding Lady (Miss Florence Petty, H.M.C.A.) gives much prominence to oral hygiene and talks on The Care of the Teeth have been given by her, as by other members of the staff.

The vice-presidents include Professor Irving Fisher, Yale; the late Horace Fletcher; Sir F. Truby King, New Zealand, as well as Dr. Harry Campbell, Dr. Sim Wallace, and Mr. Montagu Hopson. Dr. Harry Campbell is the society's chairman, while Dr. Sim Wallace is also on the executive committee. The British Medical and Dental Association and the School Dentist Society have been represented on its conference committees.

Perhaps the chief merit of the work is that its propaganda is scientific and at the same time popular.

Any further information, as well as a list of publications, will gladly be sent on application to the office, 24 Tufton Street, Westminster, London, S.W.I., Charles E. Hecht, honorary secretary.

The Problem of Dental Education in France*

PROFESSOR A. HERPIN, M.D.
Paris, France

THE DENTAL QUESTION

The dental question is one of the simplest; its clearness follows naturally upon the statement of its history. It is thus at least in France, but what we have to say of it must evidently apply with little difference to many other countries.

Before the Revolution in 1789, the citation of the name of de Fouchard is sufficient to show that this specialty was honorably followed. But the Revolution suppressed diplomas and faculties, and after the reorganization of higher courses by the law of Ventose (sixth month of the revolutionary calendar), dental science, forgotten, was not even mentioned.

On account of this its practice was open to all. Also, while the other specialties continued their progressive evolution toward medical science, dentistry remained stationary, tended to depart from the path followed by the others, and was not slow to suffer degeneration.

With no more diplomas, no more schools, no more instruction, dental science became a trade; to prepare oneself to practise it, it was no longer necessary to pursue courses, but to undergo an apprenticeship. It was no longer a question of a scientific profession. What was taught consisted of methods, tricks, prescriptions. One emerged from a training like that of the sorcerer, the professional healer, the bonesetter. This lasted almost a century.

About 1880 certain of these charlatans took a notion to make themselves known, perhaps to render service, by codifying these procedures and founding a school. But they were themselves the products of these methods, had been stamped with their mark, and could not free themselves from their environment, from their predecessors, and from a century of obscurantism. Their training was manual; their practice was the same; they could not lead their pupils except along the paths they had followed and continued to follow. And so they decreed that technic was everything in dentistry: as to science, there could be no question, on the face of it, as to that. It was thus that a precedent began to be established; moreover, most unfortunately, obscurantism was being systematized.

These organizers dreamed of nothing but defending their work, of strengthening their assumed position. They proceeded then to install themselves in an isolation from which resulted inevitably the doctrine of autonomy.

The public accepted voluntarily this attitude. It was not with impunity that, for almost a century, it fell into the habit of considering the dentist as a mysterious being, a sort of magician or prestidigitator. Also when, from a desire to keep themselves independent on the borderline of medicine, the surgeon dentists proclaimed the absolute necessity of a marvelous technic, the way was prepared, and the thesis was admitted without difficulty, in all the professions, and even in the medical profession.

Equivocation resulted, carefully fostered by the

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

leaders of the dental groups, for whom it had secured positions which they wished to keep. The groups followed afraid of a progress which would risk showing up their insufficiency and the necessity of their suppression.

These consequences were grave. In spite of general culture, in spite of indispensable clinical instruction, the surgeon dentists have remained as a whole the worthy descendants of charlatans. It is a trade that they practise, not a branch of medicine. They accomplish, by means of ritualistic gestures, results of which they cannot understand the import.

They fill cavities without knowing what dental caries is, without the power to envisage the consequences, to the other organs, of such practices; they extract because they do not know the cause of the trouble and the therapeutic possibilities; they retain teeth under conditions of which the clinic and the radiograph daily show us the dangers.

It is a trade; instruments, apparatus, everything must have a useful purpose; the value of the products is in direct ratio to their demand; today it is vaccination which is in favor, or at least what goes by that name; tomorrow the same will be true of the violet rays.

THE REMEDY

To stop this equivocation. Technic is a means but not an end; it is dangerous if the technician is not above all an expert clinician.

Are there organs that are autonomous? How can such an insane opinion be credited? All are interdependent, and so it is necessary to know general pathology well in order to practise one of its branches; it is necessary to be first a clinician in order to diagnose and to cure.

It is indispensable then to raise this specialty to the level of the others, to require that a man be a physician before he can treat patients; the raising of the moral plane will follow, and we shall do away with a trade in order finally to organize a branch of the art of healing.

The Relation of Nutrition to Stomatology*

ROBERT H. ROSE, A.B., M.D.

New York

Correct nutrition, prenatal and throughout life, should result in an approach to perfect teeth for mankind. To cite some authoritative evidence substantiating this opinion, I shall quote from Cross (1): "Good teeth are possible." "The mother more than the dentist is responsible for poor teeth or can give good teeth to the child because teeth are an organ of the body and are developed by the food just as are other organs." To show how important this is considered by Dr. Cross, who is the director of the Forsyth Dental Infirmary for Children, I shall quote a statement of his from a report of this dental institution for 1925. "This is a medical clinic (speaking of the dental pediatric clinic) with a dental viewpoint inasmuch as its object is to improve the nutrition of the child with the idea of influencing the structure and quality of the teeth. The research work carried on throughout the last few years tends to show very plainly the effect of nutrition upon the development and maintenance of the teeth and, based upon these results, dental pediatric work has been developed."

GOOD TEETH THE NATURAL RIGHT OF MAN

It seems evident that good teeth are normal and the natural right of mankind if, as Dr. Cross says, they are possible and if it can be shown that in certain countries in the past or in certain countries now they are the rule. Then we must accept this as a part of the normal healthy human being. In other words we must consider the deplorable condition of the teeth of the American people as a departure from health and a condition which we should make an effort to correct.

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

PREVENTIVE DENTISTRY

In the United States with its one hundred and thirteen million population we have approximately fifty thousand dentists. There is no question of the high degree of skill developed in their art in a technical way. They have invented many ingenious instruments, devised operations and methods of filling cavities which compare favorably with the achievements in any other line of endeavor. What they have done is thoroughly commendable. From the viewpoint, however, of preventive dentistry little has been done. If eighty per cent. of adults suffer from pyorrhea; if more than one hundred million men, women and children suffer from caries and if seventy-five million have tooth abscesses; if the teeth of children begin to decay in the temporary set and continue throughout life, we cannot say that much has been accomplished. We might say that from generation to generation there is some improvement in the methods of filling the teeth but the teeth themselves are no less subject to caries, abscesses and other conditions and are responsible for as much systemic disease. If, as recorded in literature, over forty diseases have been traced to diseased teeth and teeth are just as diseased as they were several generations ago, should we not look for other methods in an endeavor to accomplish more in the treatment of diseases of the mouth and diseases arising therefrom?

FAULTY NUTRITION IN RELATION TO POOR TEETH

The reason for the prevalence of poor teeth in this country has to do in all probability with faulty nutrition. We have given little attention to the subject of scientific nutrition. Indeed we have failed to put into practice those principles brought to our

attention. We know that our dietary is lacking in green and coarse vegetables and in fruits. Scientists inform us that it is very frequently lacking in calcium (lime). This is a significant point when it is realized that the teeth are nine tenths lime. We know that our diet has been comprised of too high a proportion of soft foods, of rich starches and fats, including a mixture of starches and fats in the desserts so commonly permitted. The consumption of sugar in this country has increased from ten pounds per capita per annum a century ago to one hundred pounds. It is said that in forty years the consumption of candy has increased ten times. Our excesses in these lines have a deleterious effect upon the teeth.

It does not seem strange when these facts are taken into consideration that the majority of people have inferior teeth. Given food which requires chewing, food which furnishes sufficient calcium, vitamines, minerals and proteins there should be a great change in our teeth. In our eating it would be difficult to depart much further than we do from a diet suitable to produce healthy teeth. Sherman states that we, as a nation, are much more subject to lime deficiency than to protein deficiency. We also recognize that in refining many articles of food we remove vitamines and minerals. In order to offset this it would be necessary to choose articles in each instance which would contain the things removed in an amount sufficient to make up for the deficiency in the refined foods. This would be a rather difficult correction to make, is not practicable and it has not been done up to the present time.

FURTHER EVIDENCE OF THE IMPORTANCE OF NUTRITION

To give supporting evidence in the matter of the importance of nutrition in the development and maintenance of good teeth I wish to quote again from Cross (2), "These observations with children show first that there are at the present time those whose teeth are normally formed and completely covered with enamel; that strong and well developed jaws with wide arches are in evidence in certain localities. Also that these conditions exist in spite of little or no care in regard to brushing, or other artificial means of cleaning, the only attention given to this feature being the unintentional one of habitually ending the meals with a salad or fruit.

Among the charts shown by Cross, Chart E is of sixty-three Italian children, average age twelve years, who arrived in 1921-1922. Eighty-eight per cent. had good teeth, one per cent. poor. Balance fair. Chart F, twenty-five Italian children, average age twelve and a half years, American born, ninety-six per cent. with tooth defects. Chart G, forty-eight Italian children, average age six and one half years, American born forty-two, two with good teeth; Italian born, six with perfect teeth; eighty per cent. with tooth defects. These observations would tend to show that the Italian born children have a prevalence of almost perfect teeth, while children of the same parents born in America have almost as bad teeth as Americans in general. To accept this statement of Cross is to recognize the great importance of nutrition in relation to stomatology—the latter being the science of diseases of the mouth. To state this relation in a few words we have in the mouth: teeth, gums and bones of the jaw. To diseases of the teeth, gums and jaw we can trace over forty other diseases. Proper nutrition, prenatal and throughout life, seems to create good teeth. It seems to render these tissues healthy and resistant to disease. The relation therefore of nutrition to stomatology is one of fundamental importance. In fact, it probably transcends all other factors.

GOOD TEETH NORMAL

That good teeth are normal I think no one would deny if they had knowledge of the condition of the teeth of the various races past and present. I think they would find too many countries in which excellent teeth predominated. E. A. Hooton (3) examined ninety-six skulls from the Peabody Museum, which were exhumed by Stefansson, these being from inhabitants of Iceland who lived in the ninth to the thirteenth centuries. He reports no decayed teeth. McCollum (4) states that skulls of several hundred Indians of two hundred to three hundred years ago in the National Museum at Washington were examined and all teeth found perfect with the exception of a few which had been broken off." These instances might be multiplied. Now which are we going to regard as normal? The condition in the United States with almost universal caries and pyorrhea, with irregularity of teeth and poor articulation or the condition in the countries where the teeth are regular, articulate well, free from caries and pyorrhea. There can be but one answer. Teeth approaching perfection are normal and the right of mankind. Diseased teeth are like diseased tissues in other parts of the body—a departure from the normal—something to be avoided.

ANIMAL EXPERIMENTATION

Zilva and Wells, experimenting with guineapigs, concluded that the teeth were among the first parts of the body to show the effects of a scurvy producing diet and they might even be markedly changed in mild cases where evidences in other parts of the body were lacking.

May Mellanby has established a similar relation between rickets and defective teeth through animal experimentation.

FAULTY METHODS OF EATING

It is simpler in endeavoring to point out how we should eat in order to produce good teeth to call attention to the faults of our present methods of eating and then show how they are corrected. The diet must contain all the elements of which our tissues are composed in sufficient quantities to build them and later to repair them and furnish fuel for life's activities. At present our chief faults are too little calcium, sometimes too little iron, too little of the vitamines, too little roughage, too much sweets, refined foods, rich foods, concentrated foods and too great a total quantity. The method of correction is as follows:

To correct the lime deficiency the dietary for the day should include two glasses of milk and two helpings of green leaves. To correct any deficiency in iron the green leaves together with a variety of food will suffice. To correct the deficiency in vita-

mines use the green leaves, two helpings of fruit, three helpings of coarse vegetables, the aforementioned milk, three or four balls of butter with two or three ounces of cream and only whole grain products. Now the deficiencies of the dietary have been covered.

We will discuss the excesses: Sugar and candy and sweets could well be eliminated from the dietary. The same is true of cake and starchy desserts.

The fats should not be taken in amounts greater than mentioned, with the exception of a small amount of olive oil and the fat of the yolk of eggs as these are eaten, unless it is desirable for preventing loss of weight for those inclined to thinness or those who are very active.

Excessive intake of protein is easily avoided if one realizes what is a normal amount of protein. An easy method of approach is the following (5):

First we must recognize that many articles of food not classed as protein food contain a moderate amount of protein. Bread is a good illustration of this. Though approximately fifty per cent. carbohydrate it is a food which contains between five and ten per cent. of protein. Figuring an average diet the writer found that in consuming about two thousand five hundred calories we obtain thirty to forty grams of protein in articles classed as carbohydrates and fats. This is almost half of our protein requirements for the day and we obtain the remainder from meat and two glasses of milk. One third of a pound of meat or fish daily is sufficient. If for any reason meat cannot be taken, milk or cheese may be substituted. One quart of milk furnishes approximately the same amount of protein that is furnished by one third pound of meat.

To show the points regarding our lime requirements and our protein requirements two tables are presented, one showing the ten best of the chief sources of lime, the other the ten best of the chief sources of protein.

The accompanying menus for one day illustrate how a proper dietary can be selected which gives the required amounts of calcium, phosphorus, iron, protein, fats, carbohydrates, calories and vitamines. It shows how the principles here enumerated may be applied.

It will be noticed that these menus for a day include a variety of food. They are not so different from our way of eating as might be expected and yet all of the points mentioned are covered. Our deficiencies have been supplied and our excesses have been eliminated. This is only commonsense but it answers all the scientific requirements. It must be recognized that in feeding our bodies we are building our tissues. We supply them exactly what they require. They are therefore properly built and should be normal in every way.

TEN CHIEF SOURCES OF LIME

(Daily requirements 15 grains CaO)

		Grains		*Requirements*
Milk, 10 oz	=	7.3	=	1/2
Cheese, 1 oz	=	5.7	=	1/2.5
Mustard greens, 2 oz	=	6.0	=	1/2.5
Turnip tops, 2 oz	=	4.2	=	1/4
Molasses, 2 oz	=	2.5	=	1/6
Bread, Boston brown, 3 oz	=	2.37	=	1/7
Oranges, 7 oz	=	1.9	=	1/8
String beans, 4 oz	=	1.2	=	1/13
Spinach, 2 oz	=	0.8	=	1/19
Bread, whole wheat, 6 oz	=	0.79	=	1/19

TEN CHIEF SOURCES OF PROTEIN

(Daily requirements 70 grams)

	Grams
Meat, 5 oz	34.5
Milk, 1 quart	33.0
Cheese, cream, 1 oz	8.0
Cheese, American, 1 oz	8.0
Bread, whole wheat, 6 oz	17.0
Eggs, 2	13.0
Baked beans, 2.6 oz	5.4
Peas, 2 tablespoonfuls	5.0
Cereal, moist, 1 helping	3.0
Banana, 3 1/3 oz	1.5

A Discourse—Wherein a Doctor Intrudes on the Domain of Dentistry*

WESTON D. BAYLEY, M.D.,
Philadelphia, Pa.

The time is near when such a title will involve a contradiction of terms, for then it may be said "How can a physician trespass if he merely scrambles over a fence on his own estate? The little isolated settlements of former times no longer exist, they are now merged into an incorporate acreage."

Dentistry of the past and much of it today is in an anomalous position. The puissance of modern medicine demands that dentistry shall broaden and develop from what is largely a mechanical art into a department of medical practice comparable with ophthalmology, dermatology and other 'ologies which after all are only centrifugally concentrated trends of general medicine. A specialist in any line cannot reach the maximum of scientific usefulness if he has not been well grounded in general practice; and similarly an internist may concisely evaluate his qualifications by gauging his degree of working knowledge of the current accomplishments in the several specialties. He must know the rudiments of ophthalmology and have it clear in his mind, that a refraction without a mydriatic is an unscientific makeshift, indulged in by optical quacks who dare not use "drops," and some oculists who will not take the necessary time to employ them. He must know that an acute hemiplegia in a young person is not a "stroke" but may mean unrevealed syphilis. He must know that an ordinary bellyache involves problems which may even elude the highest diagnostic acumen.

We can all learn from each other, and there is not even a remote possibility of any one ever reaching the sublime intellectual heights of knowing it all. Miserable, however, is the pretender who through laziness has learned nothing since he left college; because with him, the widening hiatuses in progressive information become automatically filled with vociferous prejudice and conceit; and his voice is especially loud in the criticism of later innovations in the progress of medicine, the normal understanding of which lies beyond his moss grown comprehension.

According to present day conceptions of disease, its etiology is divided into six general groups, some of which may in a manner merge. Thus we recognize psychical causes; traumatisms; degenerations and involutions; morbid growths; extrinsic chemical poisons (organic or inorganic, but devoid of life); and in the last class, living organisms—animal or vegetable—with their chemicobiological products which according to their nature and activity are more or less destructive to the vital organs of the invaded subject.

The present discussion is limited to the last of these etiological groups; or, more specifically, to pathogenic bacteria localized in some circumscribed nook of the body. This constitutes the medical problem of focal infection; and with growing observation and experience I am constrained to remark that this latest development of medical attainment is now only in the infantile stage of its ultimate importance and comprehension.

The gentlemen of the dental profession are dealing with but one manifestation of the versatile depredations of this highly organized etiological culprit. It falls to the lot of the more broadly observant physician to pursue him into his remoter Briarian lairs. In the established medical routine of inspection, we usually begin with the teeth and then proceed to the tonsils, nose, sinuses, ears, pulmonary tract, gallbladder, appendix (some say the mesenteric glands), intestine, prostate, fallopian tubes, endometrium; and time will doubtless reveal other hidden spots where pathogenic bacteria may colonize, and from thence travel with their destructive sewage in the vital streams to find landing places on remoter shores in the system, there to ravage perhaps unrestrained, like devastating pirates.

One curious and important observation concerning pathogenic bacteria is their demonstrated tendency to transition, evolution, or variation under physically altering conditions. Thus a given colony, if freely accessible to air, may remain respectable citizens of their kind, perhaps attending church services, forming antisaloon leagues, and acting generally with peaceful sobriety; but once let these nomadic settlers get locked in and be gradually deprived of air, and what happens? Do we not see the Christians degenerating into catiffs, the worthies into wretches, the saints into sinners, the deacons into demons, the pious and infallible topes into sure enough topers; and thus the whole bacterial civilization may evert from the comparatively innocuous to the actively wicked.

Another significant consideration is the fact that focal infection is not a fixed quantity, working out identically in all persons. On the contrary, it is a complex vital problem possessed of a moving scale of invasion and vulnerability, measurable in degrees at either end of the situation. Thus it is that in each afflicted person the varying quantum of invading virulency and established systematic resistance is comparable with the vacillating and endless struggles of Ormuzd and Ahriman. The particular strain of bacteria may be strongly or weakly toxic, and correspondingly the established vital resistance to it high or low. This circumstance greatly complicates the problem as it is viewed by the average layman, who naturally prides himself on what he calls his "common sense." These are our patients, the people with whom the professional man must actively deal. With many of them their only educational uplift is the press and the pulpit. And whatever else may be credited to these sources of information, no intelligent person in these days would claim for them any scientific value. On the contrary, I have even heard highly intelligent and thoughtful people express the wish that the churches be converted into lecture halls for the dissemination of useful knowledge, wherein people would hear more about health and less about heaven; more about popular medical problems and

*Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

less about Moses; or as the dentist might express it, more about teeth and less about trinities. In these passing cogitations I am far from any desire to controvert any one whose established views may take our contemporaneous theology seriously. However you may individually feel about these problems, the fact remains that doctors and dentists are educated technicians, living in contact with patients who may yet be mentally submerged in the continuing dark ages of ignorance and superstition, from which these particular humans have not yet been emancipated. The dentist, well knowing these mental limitations of his patients, has a serious problem to deal with in this more technical concept of focal infection. I venture to say that these are problems often thought over in private by doctors and dentists but seldom publicly discussed excepting by the few who have outspoken radical convictions. I have personal acquaintance with several young dentists, well qualified in their profession, but naturally striving to develop a paying practice. A new and perhaps influential patient may come in. Inspecting the denture of his new patient, our dentist may scientifically have in mind all that I could tell him about the sinister menace of infected teeth. Likely at once comes the potent argument of the layman, whose "common sense" of course outweighs what he calls "irresponsible medical enthusiasm." Naturally these people do not want to lose teeth which do not ache, and continue to function for chewing.

The layman's arguments for socalled common sense may be expressed in terms about as follows:

1. I have close acquaintance with people whose teeth are awful. They have had nasty stumps in their mouths for years, yet apparently they are in good health.

2. Friends of mine have what appear to be perfectly sound teeth. They go to their dentist at frequent intervals, yet they suffer from rheumatism, neuritis or other maladies which could be attributed to otherwise useful teeth which happen to show suspicious shadows in the x ray pictures.

3. I have acquaintances suffering from rheumatism, neuritis or what not; all of their diseased teeth have been removed to the complete satisfaction of both doctor and dentist, yet the patient shows no improvement.

These are the arguments commonly employed by certain of your patients when you try to convey to them an understanding of the dangers of focal infection; and the quaint part of it all is that as related to certain individuals, all of these empirical statements may be perfectly true; and the "common sense" reasoning seemingly triumphs, because the average layman cannot be brought to understand the varying tension in different persons, between the virulency of the invader and the activity of the defence.

The same microorganism which would proceed to a fatal endocarditis in one individual, would be promptly knocked out in the second round if it invaded another person suitably armed to defeat the enemy at the point of attack.

Varying are the results in the battles of this internecine warfare between the invading hosts and the organic defenders, and this fact lends a pseudoverity to the superficial observations of some of our patients who naturally want to keep their molars and other appendages as long as these human possessions continue to do the work for which Nature designed them.

What is more, I am in full sympathy with the layman's point of view, and would be moved by it, were I not keenly aware of a more sinister aspect of this problem, laden with hidden dangers and tragedies—real hazards, concerning which our patients are serenely and blissfully ignorant.

I have already alluded to my young, well qualified and conscientious dental friend, seeking to build up a practice, yet occasionally compelled to put the soft pedal on his conscience, lest he antagonize and lose valuable patients to the eager dental quacks who are willing to promise and perform anything. Now let me tell you something of my older friends in dentistry—men of skill and attainment who are harassed and overburdened with too much work. These excellent colleagues of mine occasionally make a slip just like that of their younger confreres, but from a directly opposite cause. The young man compromised, fearing to lose his patient; the older man overlooked his patient's hidden pathology because of hours always overcrowded, and my skilled colleague must perforce be expeditious if his patient makes no howling subjective complaint.

Thus I know of persons whose mouths glitter with golden caps, suggestive of precious stalactites at the entrance of a gold mine. These works of art easily pass the hurried and superficial inspection of a busy dentist, only in fortunate instances to be checked up later by röntgenographic studies insisted upon by the slower moving and more suspicious family doctor. At the present moment a close relation of mine whose dentist is one of my respected friends, passed the muster of his quarterly inspection. She had a beautiful piece of bridge work recently put in with fore and aft anchorage. In spite of the fact that my high class dental friend assured me that everything was all right, I had reason to insist on x ray studies of her teeth, and these showed the two bridge supports, and six other teeth, to be radically diseased. My dental friend in this case is a skilled and high grade technician. I do not hold him in the least responsible for this defection, since my relative made no complaints. He passed her along because superficially everything looked good. This case is quoted merely to illustrate the fact that even an up to the minute dentist may make a casual examination and give an opinion entirely devoid of value from a medical point of view.

Is it not, therefore, true that occasionally the younger dentist through fear, and the older dentist through oversight, may dangerously ignore some of the active etiological factors which so greatly concern medical men who are called upon to deal with the ultimate despoilation resulting from the silently hidden point of invasion of these insidious foes?

We medical men who deal with conditions remote from the purely mechanical problems of the dentist yet wherein it is clearly established that the lesion is of dental infection, are especially suspicious of capped teeth, of devitalized teeth, of pivot teeth cemented into a stump, and of fixed bridge work. We hold no brief against the dentist for his constructive endeavor, since we are aware of the entirely natural demands of our patients for mechanism to assist in mastication, and obliterate unsightly defects. These are important considerations, and doubtless in many instances the

mechanical work of the dentist is beneficial and bacteriologically harmless. But so often do we find that these devices—skillfully, safely, and usefully done at the time of their construction, later become (when not adequately watched) the primary breach in the wall, stealthily admitting those active enemies, which once holding a well established base of operation, have free opportunity to invade—with resultant incurable infections—vital organs whose normally healthful activities must now yield to the destructive will of the invading hosts. This statement is so certainly true that the doctor and the dentist should actively confer when constructive dental work is contemplated. Especially, too, must the patient be warned of the latent dangers of these otherwise useful mechanical devices; and instructed to return at safe intervals for inspection, even though there be no discomfort or complaint.

At the present time it is an open question whether or not a devitalized tooth which shows no gross pathology, is dangerous to its owner. It is not my present purpose to enter this controversy further than to remark that at least greater care should be exercised in root fillings, and an x ray picture should be made of them before dismissal of the patient. The imperfect root filling, the root filling which perforates the apex, the occasional one which leaves the canal and perforates laterally are certainly defective and likely dangerous.

There is an increasing class of dentists who have qualified in the entire pathology of the mouth; who are clinically acquainted with all of its diseases; who know the folly of trying to cure buccal infections if rotten tonsils or infected sinuses continually reinfect the areas of their work. These gentlemen, whether they know it or not, are stomatologists.

How many of us really know the pathology of the tonsils? Certainly no one is qualified to pass an opinion if he does not properly use a pillar retractor in his examinations of the throat. The ancient idea that diseased tonsils were the ones which filled the pharynx, rounded like crabapples, is not partly true. Some of the worst of them are retracted and adherent behind the pillars and cannot be seen at all by the unaided use of the tongue depressor. The tonsil must be everted and pressed upon by a retractor to bring it properly into view, and the pressure may produce cheesy, pussy or sanious exudate, which may be studied pathologically, but which in any case condemns the tonsils as etiologically dangerous.

1724 Spruce Street.

An Approach to the Study of Pyorrhea Alveolarus*

ALFRED J. ASGIS, ScB., D.D.S.
New York City

The approach to the study of the disease which is localized in the stomatological region, commonly designated as pyorrhea or pyorrhea alveolaris, either in regard to the causation or the treatment of this disease, seems to have been overlooked in the past and to have been considered of secondary importance.

A careful examination of international literature on pyorrhea discloses that the approach or the point of view adopted by an investigator or group of investigators at different periods in the state of development of dental science have borne a corresponding relation to their interpretation of the etiology and the treatment of the disease. In other words, the approach of these men has colored their deductions. It seems, therefore, that at the very outset of the study, different groups have set out on their journeys of investigation in divergent directions. With regard to pyorrhea alveolaris, there has been this marked tendency by a group known as the localists and by another group known as the constitutionalists; the former maintaining that the local cause or causes are primary in the causation of the disease and that constitutional factors are secondary and the latter group holding to the opposite view.

In this discussion it is proposed to direct our attention primarily toward finding an approach or point of view which will clarify rather than confuse the practitioner in his choice, in a given case, of one therapeutic measure in preference to another. Pyorrhea alveolaris is a subject still under investigation and no universal method of treatment has been accepted to date by the profession at large. We must keep in mind, therefore, that no statements need be accepted as final, but should be assumed to be logically true in relation to the postulated and accepted hypothesis.

I am not going to advance an hypothesis or a theory explaining either the etiology or the advocacy of a universal method of treatment. I will try to show that we need first to state the nature of the problem and then adopt a method of approach. Above all, we must set out with a given point of view and carry out our investigation, step by step in logical sequence in order to build up a scientifically sound hypothesis. This implies a correlation of clinical findings with histopathological studies. The mere collection of clinical facts is not sufficient to lay the foundation for a scientific theory, as was clearly pointed out by Poincare (1) "Science is built up of facts, as a house is built up of stones; but an accumulation of facts is no more a science than a heap of stones is a house."

In the first instance it is essential to agree on general principles, at least as to what we mean when we speak of pyorrhea. Whether we adhere to one theory of the etiology of pyorrhea or to another, we must at least agree that we are discussing the same condition which presents the same clinical and pathological picture. Whatever term we may use and according to Blessing the etiology of pyorrhea alveolaris has been considered from 350 points of view and christened with 350 names, we must agree that a given discussion refers to the same mouth lesion. By first defining our subject and stating the problem we may adopt

*Read before the Eastern Dental Society of Philadelphia, Pa., on December 3, 1925. Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

a basic method of procedure of verification of the theory.

By procedure I refer to what I should describe as a check which would correspond to a control as used in bacteriological investigations. Later on, I shall attempt to suggest to you a "check up," so to speak, on three factors in each case that presents itself, either in your private practice or in the hospital. To verify and establish the soundness of the positive value of a therapeutic measure it is necessary to have under "check" or control the following conditions: 1, focal infection must be eliminated; 2, the dietary must be regulated; 3, mouth hygiene must be maintained.

I have indicated the need of first postulating our problem, that is, it is necessary to differentiate mouth conditions which are designated as pyorrhea from a gingivitis or other mouth lesions which are not true pyorrhea. The necessity of studying pyorrhea under such conditions wherein all suspected foci of infection have been removed, where the dietary has been regulated and where mouth hygiene has been maintained cannot be overemphasized if we are to adopt a workable therapeutic method.

I wish to have it understood that the approach, or the point of view, in this paper is of major importance. If one adopts the point of view of the localist, he, at once, confines himself to a given therapeutic method, which of necessity limits his future investigation; if he adopts the constitutionalist's point of view, he, then, confines himself to another therapeutic procedure, which also limits his future investigation. There is need of adopting a point of view which will not limit one to the adherence of either theory of etiology and will still embrace the fields covered by both. The logical thing is to consider the condition of pyorrhea from the viewpoint of the interrelationship of mouth conditions to systemic disturbances. That is, having eliminated focal infections, having regulated the dietary, and, having established mouth hygiene; will the pyorrhetic condition continue to prevail? What may be the possible cause of the persistence of the condition after the removal of the vicious pathological cycle caused by local and systemic factors?

It might be in place at this point to call attention to the fact that both localists and constitutionalists have not taken cognizance of, at least not to an appreciable extent, the part played by focal infection resulting from root sepsis and general oral sepsis from improper dental prophylaxis as a factor in the causation of pyorrhea. The various theories of the etiology of pyorrhea which have been based upon clinical observation have been deduced, in a great measure, upon the disease when recognized. These theories are necessarily logical themes enabling us to account for cause and effect in the production of disease. The validity of these theories would, therefore, depend upon whether they satisfy the requirements of scientific hypothesis and whether in their applicability they produce the desired results.

From the stomatological point of view oral foci of infection must be accounted for, as I will later indicate in the explanation of the etiology or treatment of pyorrhea. The theory of focal infection has only of late received attention in Europe.

Considering pyorrhea from the point of view of the relationship of the condition of the mouth to the systemic condition, that is, approaching the problem from the stomatological point of view and with the case checked, we may then hope to postulate an hypothesis or theory of the etiology of pyorrhea with a certain degree of scientific exactness. I will present the views held by different authors as to what is pyorrhea and what is not and in what measure there is an agreement as to its etiology.

On my recent visit to Germany I had the opportunity of hearing the various views expressed by leading European authorities on this subject. I had the pleasure of hearing Professor Romer speak on pyorrhea on the occasion of the reception of the American Stomatological Committee in Berlin. He speaks (2) of pyorrhea as a typical alveolar pyorrhea which can be considered as the final stage of all forms of the socalled paradentosis. With regard to the clinical picture, as expressed by the condition designated as pyorrhea, he referred in the following terms: "The clinical picture of the alveolar pyorrhea is well characterized. This disease has been named thus, because its most striking symptom consists in pus oozing from the gum pockets pathologically deepened when the teeth always gradually loosen and at last fall out, because the ossific alveolar parts disappear gradually, down from the neck of the tooth to the extremities of the roots. Here the loosening is not confined to a single tooth but whole groups of teeth are always attacked and in serious cases even all the teeth of the upper and lower jaws."

Gottlieb (3) holds that in pyorrhea the condition is not localized in the tooth, and he differentiates three conditions; namely, filth pyorrhea, paradental pyorrhea and alveolar atrophy. Gottlieb points out that in the early stages of socalled filth pyorrhea, it occurs practically without pyorrhea alveolaris, and he maintains that in the early stages of the diffused atrophy of the alveolar bone, no indication is present to show any inflammation of the gum tissues.

Pickerill (4) distinguishes three conditions leading to pyorrhea; namely, gingivitis, dental arthritis and pyorrhea alveolaris. Acute gingivitis is attributed to bacterial infection or mechanical irritation, both of a local character. It not infrequently arises apparently through infection of the gingival tissues by the normal mouth bacteria, when the patient is subjected to particularly heavy stress of work, rather mental than physical or when the surroundings are unhygienic. The localized form is usually associated with some kind of mechanical irritation in connection with the teeth, such as wires, clasps or bands used to retain artificial dentures or to regulate teeth, or to the overhanging cervical edges of crowns or fillings.

Regarding the clinical picture of pyorrhea, he maintains that it is extremely rare that pyorrhea is confined to the gums proper. The joints between the teeth and the jaw bones become involved by the upper part of the periodontal ligament becoming infected. Thus a dental arthritis is set up, which may be simple at first but may become later suppurative. The condition then may be called an acute pyorrhea alveolaris.

Here, too, we note that a careful distinction is made between a gingivitis and a dental arthritis. When the hypertrophic and suppurative (5) forms of gingivitis are associated with dental arthritis the latter is or rapidly becomes suppurative also; we have present

then the disease long known as Rigg's disease or pyorrhea alveolaris (alveolar osteitis or suppurative marginal periodontitis).

The various terms used to designate the same pathological conditions and the same clinical picture, as employed by the different authors, as indicated, include the following: Black, "phagendenic pericementitis"; Talbot, "interstitial gingivitis"; Riggs, "Riggs's disease"; Greve, "caries alveolaris idiopathica"; Romer, "periodontitis chronica marginalis purulenta"; Witzel, "alveolitis infectiosa"; Magitot, "osteoperiostitis alveolodentalis"; Galippe, "gingivitis arthrodentaire"; Arkovy, "caries alveolaris specifica"; and others.

Another classification of pyorrhea, from the viewpoint of pathology, was presented by Cieszynski, as follows: I. Atrophia alv. idiopath, a, nonpyorrhea; b, pyorrhoica. II. Paradentosis (paracementosis) alveolaris pyorrhoica, a, marginalis; b, intraalveolaris. III. Atrophia alveolaris idiopath. et Paradentitis alv. pyorrh., a, marginalis; b, intraalveolaris.

Moorhead and Dewey (6) define pyorrhea as: "a chronic suppurative or nonsuppurative inflammation involving the alveolar process, the periodontium, the gingivæ and the ligamentum circulare and resulting in loosening and loss of the teeth."

According to these authors (7), pyorrhea is an osseous lesion: "The main characteristic pathological processes in pyorrhea are atrophy of the alveolar process, destruction of the periodentium and the formation of granulation tissue."

In 1901, Greve (8) pointed out the inadequacy of the term pyorrhea alveolaris as a term designating this disease, because the flowing of pus in any condition of the mouth, which involves only the gum pocket, may be mistakenly designated as pyorrhea. He emphasized the fact that the seat of true pyorrhea must be considered to lie and must be searched for in the alveolar bone and not in the gingive.

The symptom of flowing pus as an indication of the presence of the socalled pyorrhea has had its practical disadvantages, for from the clinical side the disappearance of pus has been recognized as a sign of cure. In 1914 Weski called attention to the secondary importance of the symptom of oozing pus in the diagnosis of pyorrhea. He points out that in cases where no pus was present, and which would clinically be considered free from pyorrhea, when röntgenologically examined with gutta percha points as indicators, these cases showed deep pockets and indicated the transitory form of horizontal atrophy of the bone to vertical atrophy of the bone. The therapy, whatever the cause, would therefore be the same in these cases as if pus were present. Weski (9) lays particular stress as regards prognosis, on diagnosis whether we deal with horizontal or vertical pyorrhea. He does not depend on the röntgenogram exclusively for the differential diagnosis in determining the presence of a horizontal or vertical atrophy, he depends also on the depth of the pocket and the general process of the disease in relation to the bone.

Weski (10) distinguishes vertical and horizontal bone atrophy and maintains that the horizontal absorption is more favorable from the viewpoint of recovery and the reduction of gum inflammation accompanied in pyorrhea than is the case with vertical bone atrophy.

The interpretation of the röntgenogram for diagnostic purposes is emphasized. Haber (11) calls attention to the possibility of noting a vertical atrophy in one instance and a horizontal atrophy in another instance by change in the angle in the taking of the röntgenogram.

The vast amount of work which has been done in bringing the study of this disease, either as regards its etiology or treatment, under some form of scientific approach, dates back to Fouchard (1746), Jourdain (1778), and Hunter (1780). The term pyorrhea alveolaris was first introduced to designate this disease by Toirac in 1839. Although the term has remained the same and to all practical purposes will probably remain the same, the meaning has been modified and almost totally changed.

Since Hunter's emphasis on the fact that the seat of the disease lies in the alveolar bone, the etiology of the disease has been studied both from the viewpoint of the local factors as well as from the standpoint of the constitutional disturbances. More recently Weski (12) has advanced a synthetic theory that, from his clinical observations and pathological studies he contends that this disease, occurring in the paradentium, is bicausal and not monocausal. That is, the internal or endogenous causes which are the constitutional disturbances and which may occur either singly or in combination and the external or exogenous factors, which may be calculus, ill fitting bridges and crowns, overhanging edges of fillings and the excessive use of some teeth.

A survey of the therapeutic measures advocated by the various authors may enable us to determine as to the positive specific value of a given treatment. Romer recommends a corrected dietary, plenty of fresh air, cure baths, local surgical treatment according to the radical surgical treatment by Neumann. The use of pacquelin, a preparation by Romer (13) for the obliteration of pockets, gum massage, bridgework and removal sliding bridge planes.

Kantorowicz (14) recommends for the treatment of pyorrhea (paradentitis) the removal of calculus, correction of overhanging edges of fillings, crowns and bridges, thorough mouth prophylaxis by the patient, the eradication of gum pockets and of bone pockets.

Gottlieb (15) suggests for the treatment of alveolar atrophy the relief of occlusal stress by proper bridgework, proper fixation of teeth and mouth hygiene. To strengthen the bone he advocates medicated baths and corrected dietary.

According to Krantz (16) the treatment consists of the removal of calculus, the use of medication and gum massage. Krantz lays stress on the local surgical treatment.

Neumann (17) advocates the radical surgical method known under his name. He emphasizes the need of massage, more especially vibration massage.

Monier (18) has given an effective method of surgical treatment of pyorrhea.

Euler (19) proposes six therapeutic measures which when properly employed will be effective in the cure of the disease in the early stages. These measures include the removal of calculus with mechanical or chemical means; the overcoming of infection by the use of salvarsan, Deutscharan serum or pyocyanase, the removal of granulation tissue, the use of radium

and massage in the form of vibration massage as indicated by Kieffer and Fleischman.

These therapeutic measures are advocated by the localists, adherents of the theory that pyorrhea is caused either by calculus forming a pus pocket or by infection. The Karolyi localists recommend elevating crowns for the correction of the occlusion to relieve the occlusal stress of the affected teeth.

Arkovy in 1894 speaks of the localists, the constitutionalists and the fusionists and their respective methods of treating pyorrhea. It is interesting to note that he divided the localists into three subgroups as indicated above, the third of which deserves our special attention. He refers to this group as the one which maintains the cause of pyorrhea to be "the disturbance of balanced occlusion of the jaws which produces coincidentally a false occlusion of individual teeth which brings these teeth into a condition of undue occlusal stress" (20).

Among those advancing the theory of occlusal stress, Karolyi (21) of Vienna is the outstanding exponent who since 1894 attributed the cause of pyorrhea to abnormal occlusal stress of the individual teeth.

In recent years other European investigators have renewed their interest in this theory; we have among them Bodot, Falke, Weski, and most prominent of all, Peter of Vienna.

This theory of traumatic etiology in the United States is associated with what is commonly known as periodontology. The adherents of this theory in the United States, the periodontists, attribute the primary cause of pyorrhea to be what is designated as traumatic occlusion which is synonymous with the term occlusal stress, advocated by Karolyi. Among the American exponents of this theory we may mention Stillman (22), McCall, Box, and others.

To correct traumatic occlusion whether due to restorations producing excessive vertical stress or where it occurs on natural teeth with no restorations, it is necessary to grind the occlusal planes off the teeth, which reduces the actual height of the tooth, thus making the occluding surfaces lower.

Talbot (23) divides the disease into six groups for purposes of treatment. He is interesting and suggestive, for he maintains that group five and group six must be handled by the physician, because in these cases so many other bodily symptoms are present and need to be considered first. With regard to local treatment in all cases, except those of anemia of the gums (group five) he advocates the removal of the deposits, the use of iodoglycerol every second day and the free use of the gum massage brush.

A survey of the various methods of treatment may for purposes of our discussion be divided under two headings, namely, 1, the treatment of the mouth locally; 2, the treatment of the body constitutionally. The former refers to the establishment and maintenance of mouth hygiene by local measures, such as the removal of calculus, the obliteration of pockets and gum massage; the second, constitutional treatment lies entirely with the realm of general medicine.

Let us now consider briefly the place that is given to oral focal infection and dental prophylaxis in regard to the treatment of pyorrhea. In a symposium on periodontia practice (24), among the nine steps recommended for the treatment of pyorrhea, we note the capping of teeth or the devitalization of pulps.

Notwithstanding the clinical and experimental evidence to the contrary, it is generally accepted that regeneration of tissue may be expected around teeth from which healthy pulps have been aseptically removed and whose canals have been properly filled. But a complete response of the regenerative forces is prevented if the general resistance to infection is lowered by the presence of systemic disturbances (25).

Rosenow (26) has shown that dead teeth, pulpless teeth or devitalized teeth, with the methods now available for the aseptic root canal treatment, are foci of infection and constitute a factor in the causation of systemic disease. He, furthermore, showed by experiments on dogs that conditions of hygiene and diet which were adequate to maintain weight and health in normal dogs were inadequate for dogs harboring foci of infection. The harm, therefore, from improper food or hygiene may be greatly exaggerated by bacteria harbored in foci of infection, a point not yet sufficiently considered."

Price (27) maintains that dental infections are in causal relationship to the disturbances in calcium metabolism. Infections may bring about metabolic changes and result in a variety of ill effects on the human body (28). We note then a vicious pathological cycle persisting in the presence of oral foci of infection. It has been clinically demonstrated that many of the cardiovascular diseases of the middle and late years of life originate in severe disease of early life through the circulation of virulent toxins of streptococcus. The degenerative types of eye lesions are seen to be the result of slow absorption of toxins of streptococcus from dead teeth (29).

Is it not suggestive to suppose that oral focal infection may similarly have a causal relationship to alveolar bone changes? Hess (31), Howe (30) and others have pointed out the relationship between proper bone formation and nutrition.

Moral (32) has pointed out the relationship between endocrine disturbances and pyorrhea alveolaris. At the same time Osborne (33) called attention to the relationship of focal infection and endocrine disturbances. Here, too, it is plausible to suggest a vicious cycle as regards focal infection, endocrine disturbances and pyorrhea. If we consider that neither dentists nor physicians are agreed on this subject of oral focal infection (34) and that dead teeth are not considered as foci of infection, to what extent are the clinical records and general deductions valuable with regard to establishing the etiology and treatment of pyorrhea?

While attention was called to the importance of gum massage as a therapeutic measure in mouth hygiene and for this purpose among the means suggested prior to 1898 we find the linen cloth wrapped around the finger, cotton rolls and hard food, later on in 1908 vibration massage was advocated by Kieffer, Fleischmann and Sorup and others (35), (36).

It is also interesting to look into the matter of so-called "oral hygiene," oral cleanliness in the United States, which refers to dental prophylaxis and which is advocated as a preventive measure in the prevention of pyorrhea. Stress is being laid on the brushing of the teeth (37).

(To be concluded)

Practical Therapeutics

THE USES AND THERAPEUTIC VALUE OF YEAST AND MORE PARTICULARLY OF DRIED BREWERS' YEAST

C. FAUST NEWTON, M.D., Ph.D.
New York

As far as is known yeast was first prescribed by Hippocrates and Dioscorides, who recommended it in the treatment of leucorrhea. To them yeast was—well, just yeast—a substance. To us, in the light of modern science, the yeasts open up a whole world of their own which is still far from being wholly explored and understood.

To begin with yeasts are living organisms and more than five hundred families of true yeasts have been recognized, besides an even larger group of species so closely related to the true ones, as to have been very frequently confused with them. They multiply extremely rapidly by budding, mostly without any sexual movement, although in some families fertilization takes place through the end spores.

In composition and action yeasts are very complex and undoubtedly we have still much to learn about them. Leaving aside all reference to "fermentation" and its causes, we find that yeast cells, alive or dead, possess remarkable chemical and therapeutic properties attributable in part to their composition and in part to catalytic action.[1]

In the mind of the public—and perhaps to some extent in that of the profession—the word "yeast" immediately evokes the idea of vitamines. Brewers' yeast, particularly, has been found to be the most prolific source of vitamine B, the mysterious growth factor, and to contain traces of vitamines C and D. Naturally this led to the widespread use of yeast in nutritional and allied diseases, and, rather unfortunately, to a tremendous publicity campaign in which yeast and vitamine preparations were heralded as curealls without any regard to the origin or culture of the preparations exploited. At the same time not enough attention was given to other properties and component parts of the yeast cell.

It contains carbohydrates, fats, albuminoids. It has zymase, invertin, diastase, endotrypsin. It also contains phosphorus and lecithin. Recent investigations have succeeded in isolating from it a hormone-like substance, and have shown the existence (though not isolated) of a substance similar to insulin. It is evident that such a composition has innumerable possibilities of therapeutic application, if handled correctly and scientifically, instead of as a universal nostrum. On the other hand, if improperly used, i. e., if the preparation used is of impure culture and origin, results may be entirely negative.

Such negative results were encountered all through the middle ages and later, so that yeast was entirely eliminated from medical practice, although maintaining itself as a popular remedy in some countries, for instance in Mexico for smallpox and in France for furunculosis, bronchitis, and other conditions. The credit for its socalled rediscovery belongs to Neumann, a German physician, who in 1830 successfully used it for scurvy. Then, in 1897, Büchner isolated zymase, and about the same time Brocq in France and Lassar in Germany introduced it widely in therapeutics. Since that time its use has gradually increased in Europe, keeping pace with advancement in laboratory research. In the United States remarkable strides have been made from the purely scientific angle of the problem, but the profession as a whole has hardly begun to realize the many applications of yeast, particularly since it has become available in concentrated and palatable form, with all the advantages and none of the drawbacks of the fresh product.

It is manifestly impossible to cover the entire field of yeast therapy in a single article, so I shall lay stress especially on dried brewers' yeast, because a great majority of investigators have found this to be the most effective form. It has been shown by the Connecticut Experimental Station (Bulletin 240) to be superior to bakers' yeast, which has a lower vitamine content and is lacking in cholin and to some extent in lecithin.

Broadly speaking, brewers' yeast, dried or fresh, has been found effective in the following conditions:

1. Dermatological and cutaneous affections, and wherever pus forming organisms are a factor.
2. Deficiency diseases and certain debilitating conditions.
3. Gastrointestinal disorders.
4. Some general systemic diseases.

It also has a definite and logical place as a dietary and nutritional factor.

In the following review some applications may strike us as medical curiosities which we would not care to follow too closely; but by far the greater number of them are intensely interesting and would seem to place at the disposal of the practitioner an inexpensive and efficient therapeutic agent, whether used alone or as an adjunct to general treatment, and which is devoid of possible unpleasant aftereffects.

DERMATOLOGICAL AND CUTANEOUS AFFECTIONS

The French were the first to make extensive use of yeast in skin affections, and, generally speaking, with complete success. Fresh yeast, applied locally, had been in popular use for centuries, and German physicians report its successful use today in this form. But Brocq, Bolognesi, Faisan, Doyen and other authorities of equal weight soon began to administer it in dried form, internally (7, 27). French medical literature from 1900 to 1910 and later is filled with innumerable reports of cases treated with yeast in the Paris hospitals, including furunculosis, erysipelas, indolent chronic ulcers, acne vulgaris and rosacea, erythema urticaria, psoriasis, and ulcerative tonsillitis[2] (7, 27, 5, 19).

The average dose is three to five tablespoonfuls a day. More recently Mason (38) summarizes these applications as follows: "Yeast is serviceable in the

[1] It has been asserted that this does not represent true catalytic action, in which the catalyst itself remains unchanged, while causing or hastening changes in other substances. Yeast cells are gradually modified by the processes they cause and gradually lose their catalytic power.

[2] Hawk obtained the same results in most of these affections (25), including neuritis, arthritis deformans and rheumatic arthritis.

internal and external treatment of infections in which the staphylococcus pyogenes aureus and other pus forming organisms are factors."

American physicians who have tried yeast in these or similar cases are enthusiastic in its praise, wherever a carefully selected and thoroughly tested product has been used (25). Thus Dr. Gerstenberger (22), of Cleveland, reports nine cases of herpetic stomatitis and herpes labialis at the Lakeside Hospital which were successfully tested with a commercial preparation of yeast.[3] It appears well established that dried brewers' yeast has a decidedly beneficial effect in smallpox. D'Herbonnez (27) cites fifty cases in the Paris hospitals, treated with yeast, sometimes to the exclusion of all other treatment. In all instances there were resultant decrease in temperature, drying up of the vesicles and absence of suppuration. Other authorities mention similar observations.

Numerous factors may contribute to the action of yeast in these diseases. In general we may accept the explanation of modern American investigators (Dr. Robert McCarrick and others) that the vitamine B and possibly some other substance in the yeast markedly increases metabolism and aids the tissues in resisting infection.

YEAST IN DEFICIENCY DISEASES

In this group of diseases it is the vitamine B factor that plays the greatest part, and it is therefore of the utmost importance that the preparation used be reliable and tested as to vitamine content. It is only within the last decade that American scientists have discovered the underlying causes for the great efficacy of yeast in this field, and of the startling results which amazed earlier investigators all the more since they could not fully account for them. It was Seidell (44-47) who showed brewers' yeast to be the richest source of vitamine B, and Osborne and Mendel and others have fully covered the ground.

Dried brewers' yeast has been found almost indispensable in the treatment of beriberi (13-31), scurvy (26-32), rachitis (32-55), sprue and pellagra. Indeed, the United States Public Health Service, using the same commercial preparation used by Gerstenberger, calls it a specific for pellagra.

In rachitis it was again the French who first discovered favorable results, which they attribute in part to the phosphorus present in or radiated by yeast. Recently, Hess, McCann and Pappenheim (55) in their investigation of rachitis found casein alone to be ineffective in its treatment, but very potent when combined with yeast.

The classical experiments with polyneuritis in pigeons and the growth experiments on white rats are so well known as to need no further comment here.

Less widely realized is the practical application of the white rat studies to infants and backward children. There is no room left for doubt as to the value of a yeast addition to the diet of poorly developed and under nourished children (for instance as a flavoring in soups, etc.). Dr. Reyher (57) in 1922 reported on the successful treatment of forty-seven prematurely born infants. He administered daily one gram of dried yeast powder to the kilo of body weight and observed marked improvement in general vitality and particularly in weight.

[3]The product used was Yeast-Vitamine Harris, a product of the Harris Laboratories, Tuckahoe, N. Y.

YEAST IN GASTROINTESTINAL DISORDERS

So much has been written on its value in this field that I shall merely touch the more important points. To begin with, the remarkable experiments of Kleeblatt (34) on himself and some colleagues show that dried brewers' yeast stimulates the general secretion of gastric juices, an average increase of thirty to thirty-two per cent. being noticed, with more rapid development and longer period of activity. This led Heinz (28) to call it a stomachic and to recommend its use in tablet form in all disorders of the stomach and intestinal tract. Murlin, Raymond and Waltill (40) made clinical and laboratory tests of the value of yeast as a laxative. They found that dried yeast, while less effective in this respect than the fresh product, still retains its laxative property. Faisan (27) (40) stopped diarrhea with it, and successfully treated ten test cases of typhoid fever. They showed decrease in fever and rapid improvement in the excretions and the conditions of the intestinal tract. When the yeast treatment was interrupted the disturbances reappeared. He administered three or four teaspoonfuls three times a day. At St. Antoine Hospital, Professor Hayem (5) used a similar treatment for cholera infantum, acute enteritis, chronic enteritis, mucomembranous enteritis. He varied this with yeast enemas, but with less apparent success. Briefly then, it can be considered that yeast, preferably the dried brewers' product, is an invaluable adjunct in the treatment of almost any intestinal disorder. This is logical if the yeast composition and action are considered. The only surprising thing about it is that the profession has not used it more extensively.

YEAST IN CERTAIN SYSTEMIC DISEASES

Diabetes.—Yeast has the property of disintegrating sugar into carbon dioxide and alcohol. This led to to its being tried in the treatment of diabetes mellitus. Cassart (49) Bolognesi and Brocq observed decreased glycosuria and increase in weight and carbohydrate tolerance. Later investigators appear to hold varying views as to the reason for the action of yeast in this disease. Some maintain that it assists in changing the carbohydrates into dextrose; Lenne (36) believes its effect to be due to a hormonelike substance which it contains. Others recommend its use in conjunction with levulose or insulin, because of its vitamine B content. Euler and Myrbach (15) assert that it contains an antidiabetic substance, related to phosphorus metabolism, and physiologically and chemically close to insulin. Funk and Corbitt (21), on the contrary, point out that the effect of yeast in diabetes is very different from that of insulin, being slower but more lasting. They also think that crude yeast tends rather to raise than to decrease the blood sugar content; but from carefully grown cultures they have isolated an antidiabetic preparation.

In any event, regardless of the biochemical side of the question, the evidence is preponderantly in favor of the administration of dried yeast, provided a pure and careful selected product is used, as an adjunct to the general treatment of diabetes. The dosage must be left to the judgment of the attendant physician. As much as fifty grams daily have been given by mouth, and again only two tablets of a concentrated commercial preparation have been used three

times a day. Some practitioners have injected watery solutions of yeast; but this seems hardly a course to be recommended. The effect of yeast is particularly striking on diabetic ulcers.

YEAST IN TUBERCULOSIS

We find no record of any cure by the use of yeast alone. There are, though, numerous cases in which yeast, dried or fresh, has had a helpful influence. Cassart reports that large doses, from one to three ounces three times a day, reduced temperature and night sweats, and increased weight. Tuberculosis does not seem to be influenced by bakers' yeast. This is possibly due to the fact that the latter contains less vitamine B and is totally lacking in cholin, which, according to Ludwig, attacks the fatty envelope of the tubercle bacilli (*27, 27,* 32).

YEAST IN GRIPPE, PNEUMONIA, BRONCHITIS, AND TONSILLITIS

These are all favorably affected by dried brewers' yeast. Numerous case histories will be found in the voluminous literature on the subject, which fully justify the practitioner in using it freely (*7,* 8, 19, *27,* 25).

Interesting, though not conclusive, are the recent experiments of Urechia and Mihalescu (50), who injected a solution of brewers' yeast in ninety-one cases as a pyretogenetic agent. They found marked leucocytosis (20,000) and believe that injections of salvarsan made during the fever produced are especially well borne. They combine the spirillicidal effect of fever and arsenic. Their best success was obtained in cases of neurosyphilis.

In closing, it is well worth suggesting the use of dried brewers' yeast as a food tonic. It is similar in flavor to beef extract, and, according to Dr. Cowgill, of Yale, is superior in effect. German tests have shown that its flavor is preferred in soups, for instance (43).

In all cases of general debility it is a valuable addition to the diet, because of its vitamine B content. The lecithin it contains is a builder of bones and brain according to Burow, Fuerst, Sauceraux and Tolenatschev; it supplies nerve energy according to Koch; and increases the hemoglobin content of the blood, according to Danilewski. It is a preventive of arteriosclerosis, anemia, and scrofula. Chemical tests (37) have shown that the lecithin contained in brewers' yeast (in the phosphatides) is more closely related to that present in the human brain (kephalin) than is the lecithin in any other substance.

SUMMARY

1. Yeast, because of its composition and action, can play a far more valuable part in therapeutics than has been accorded to it. Dried yeast is as effective as the fresh product.

2. It is essential that a thoroughly pure and tested yeast preparation be used, preferably from brewers' yeast, which has a greater content of vitamine B, lecithin, and cholin than bakers' yeast.

3. It is not only a medicine to be taken in time of illness but can be recommended by the physician as an addition (in disguised form) to the diet, wherever a tonic, body or nerve builder is indicated.

FUTURE STOMATOLOGY IN THE UNITED STATES

Considerable misunderstanding has reigned as regards the status of the now practising dental surgeons in the United States during the socalled transitory period. A preliminary report covering the plans for this period was read at the annual stomatological convention in April by Dr. George Reese Satterlee, chairman of the Council on Education and Hospitals of the American Stomatological Association. The association's educational plan for the training of dentists in the future as medical specialists has been explained in detail in an article in the *Atlantic Medical Journal* for February.

The next great issue that the American Stomatological Association is taking up is the fixing of this "transitory period." A preliminary discussion of the subject took place at the meeting held in New York city on December 16, 1925. The proposed plan is as follows: That the American Stomatological Association shall issue annually a stomatological medical register containing the names of dentists who have obtained additional training in medical subjects: 1, That this official register will facilitate cooperation between physicians and stomatologists, whose names shall appear in the register; 2, that hospitals and dispensaries may thus be aided in making their appointments of dentists and stomatologists by using the official register; 3, that registration shall be an assurance to the public and to the professions that the practitioners have had the necessary training in medical as well as in dental subjects; 4, that registration shall be limited to duly graduated and licensed dentists and also to physicians who devote themselves to stomatological röntgenology and who have obtained a certificate of proficiency to that effect from the American Board of Stomatology; 5, that registered stomatologists shall, during the transitory period, have all the privileges accorded to other medical specialists; 6, that registered stomatologists shall be entitled to active membership in the American Stomatological Association; 7, that the American Stomatological Association shall make every effort to have registered stomatologists join the American Medical Association and their local medical societies; 8, that the American Stomatological Association strongly urge that the American Medical Association accord to registered stomatologists the privilege of associate fellowship by virtue of their registration.

The American Board of Stomatology has for its objects, 1, the establishment of standards of fitness to practice stomatology; 2, the working out of plans of instruction suitable for special needs of practising dentists and physicians; 3, the gathering of data pertaining to facilities on hospital staffs, dispensaries, and clinics, with regard to stomatological services; 4, cooperation with hospitals and clinics in procuring registered stomatologists for appointments. Membership of the Board of Stomatology shall be composed of representatives of the American Stomatological Association, the Postgraduate Medical School of Stomatology, and other professional societies directly concerned with stomatology; examining members shall be appointed for three years; state stomatological societies shall each have one representative appointed for three years, and an advisory board shall be composed of dental and medical educators appointed by the Board from time to time. The function of the Board shall be, 1, to hold examinations at the annual stomatological meetings of the American Stomatological Association to pass on applicants for admission to the register; 2, to issue certificates of proficiency to those applicants who have fulfilled the requirements of the Board setting a standard for the practice of stomatology.

The Postgraduate Medical School of Stomatology, chartered by the University of the State of New York, but supervised by the American Stomatological Association, is governed by a School Council, consisting of representatives from the association, faculty members, and members of the Board of Trustees of the School. This was the first school of stomatology to be established in America, and is the only school in the country that has the endorsement of the International Stomatological Association, which officially represents stomatology throughout the world and establishes the standards of the teaching of stomatology in the schools of the various countries. The purpose of this school is to give to graduated and duly licensed physicians and dentists an opportunity to obtain systematic instruction in stomatology in the United States of the same type as that afforded to medical practitioners and stomatologists in the cities of Europe. The school aims to draw into its classes those practitioners in medicine and its specialties and those dental practitioners who wish to keep abreast of the progress of stomatology in relation to general medicine. Another educational need that the school will endeavor to meet as its resources increase is that of the professional instruction of qualified stomatologists. For those who are interested in public health work the school will afford a special opportunity to

obtain instruction from members of its teaching staff who have attained distinction in public health activities. The courses are arranged to meet demands in this particular field.

The school's clinical facilities are of an exceptional nature, since it has teaching and lecturing affinities with several of the leading medical institutions in New York city and other eastern cities. The physiological laboratories of University and Bellevue Hospital Medical College are at the disposal of students who are qualified to carry on research in dietetics and other problems pertaining to stomatology. Dr. Joseph Colt Bloodgood, clinical professor of surgical pathology at Johns Hopkins University Medical School, will receive special students in the Surgical Pathological Laboratory there, and will give a special course during June and September. Fordham Hospital, with its wealth of clinical material, is available to students, as are also the McClintock Memorial Laboratory and the Medical Laboratories Incorporated, under the direction of Professor Darling, radiologist.

The courses are open to duly qualified practitioners of medicine and dentistry approved by the committee on admissions. Others engaged in public health work may be admitted by special permission. The curriculum includes stomatological bacteriology, dietetics in stomatological practice, stomatological hygiene, stomatology and internal medicine, stomatology and focal infection, physical diagnosis, stomatology and public health, stomatological surgery, stomatotechnic (reconstructions), history of stomatology, röntgenology, clinical dietetics, anatomy of the stomatological region, physiology of stomatological hygiene, stomatological diagnosis, anatomy, physiology and pathology of the head, diagnosis and treatment of mouth lesions, and stomatological pathology.

The school year is divided into three school terms each of ten weeks' duration. Each course consists of twenty lessons, or two terms. The spring term begins in October, the winter term in February, and the summer term in June.

The study of diseases of the mouth has for a long time been considered as a subject of great interest to the medical profession in Europe. In Italy, Hungary, Roumania and Austria, only those who have a degree of M.D. are legally permitted to practise stomatology. In France, Belgium, Germany and other countries there are schools for the teaching of this branch of medicine. Within the past few years there has been an increasing interest in stomatology in the medical and dental professions in the United States. Practising physicians have realized the need of more knowledge of diseases of the mouth, and dentists have been eager to acquire additional information concerning the medical side of their profession. These needs are what the Postgraduate School of Stomatology is able to fill by means of its inclusive curriculum, lecture courses, and clinical opportunities.

RADIUM TREATMENT

There is still some difference of opinion as to the efficacy of radium and x rays in the treatment of disease. There are those who doubtless claim too much for this form of treatment while there are others who are inclined to minimize unduly its therapeutic virtues. As a matter of fact the truth lies in the mean. Radium and x rays are not a panacea but are extremely useful both by themselves and in conjunction with other methods, principally with surgery.

The British Medical Research Council issued recently a pamphlet in which the effect of the uses of radium on malignant and nonmalignant diseases is summarized. Five of the centres to which reference is made are in London hospitals, and four are in hospitals in Birmingham, Cardiff, Aberdeen, and Dublin.

The experiments have been carried out with a stock of radium salts which had been collected for military purposes during the war. Further quantities of radium salt had been provided by the British Empire Cancer Campaign. As might be expected special attention has been devoted to the effect of radium on cancer. The conclusion reached is that its value varies considerably with the site in the body and the histological character of the malignant growth.

As for cancer in the breast, it is stated that radium has a definite therapeutic value, local recurrences, treated by the method of surgical insertion, are often held in check, and may disappear sometimes after the employment of comparatively large doses of radium.

With regard to internal cancer affecting the generative organs of women, it is stated that as a palliative radium treatment has undoubtedly proved itself to be of the first value. Hemorrhage ceases in most of the cases, the local growth disappears in a large percentage, the patients feel better and put on weight, and in many instances life is prolonged. The histological evidence shows that where the growth is localized the malignant cells have been destroyed completely in certain cases.

The value of radium therapy in malignant growths of the mouth, nasopharynx, larynx and esophagus is stated to be bound up intimately with the technic employed. The irradiation of tumors in such sites, by numerous, though weak, radium sources, applied for a long time is a hopeful development, but results upon a larger number of cases are needed before any definite conclusion upon this technic can be arrived at.

Another conclusion drawn is that radium therapy is effective in a large proportion of rodent ulcers. There is, however, a tendency for recurrence of these growths. In cases where there has been a recur-

rence of activity of the cells at the surface of the growth it points to unusual resistance of such cells to irradiation.

It is a fact that the value of radium depends largely on the manner in which it is administered. A great deal of the technic of radiology is extremely complicated and in order to obtain from the method its best effects the operator must be thoroughly trained in its use. Indeed, as much skill is needed properly to apply radium or even x rays as is required for the accurate performance of surgical or bacteriological work. This point is not known generally to the layman and is apt to be overlooked. Another point which is often neglected is that to obtain the most satisfactory results from radium or x rays the cooperation of the surgeon and radiologist is a question of the greatest moment. An idea seems to be more or less prevalent that radium or x rays can stand by themselves, or rather that they can replace the surgeon, or worse, the view that an antagonism exists between surgery and radiology. This view has led to mistakes in the immediate past. A copartnership between these two branches of therapy promises the most encouraging outcome. And working towards this end continued research is demanded in the field of radiology and in that field in which the surgeon and the radiologist work together. Radiology, in short, is a valuable aid to surgery. Sometimes invaluable, in some cases it is effective by itself, but as a rule it is an aid to operative measures and it is in earnest cooperation between the surgeon and the radiologist that the best hopes for the future rest.

VOLTAIRE AND PUBLIC HEALTH

Many great writers have been dyspeptic or troubled with ill health all their lives and yet reached a green old age. Some famed writers have been virulently dyspeptic, surcharged with bile and yet almost seem to have enjoyed their bad health. Among this illustrious company were Charles Darwin, Thomas Carlyle, the dyspeptic *in excelsis* who frequently poured out bile in his writings, Samuel Johnson, Herbert Spencer, and last but not least Voltaire. Like many another man who lived to be old he was a puny infant and was in the habit of complaining throughout his long stay on earth that he was on the brink of the grave. He died at the respectable age of eighty-four from kidney disease accelerated by an overdose of opium. It is said now that the stories of the anguish and remorse of his later days do not seem to rest on any sound foundation.

Dr. J. D. Rolleston in a recent lecture at the Royal Society of Medicine referred to several features of Voltaire's life of interest to medical men. In his wonderful correspondence Voltaire was one of the best exponents of the lost art of letter writing; he was impressing constantly upon his friends the importance of temperance, especially in food, and Dr. Rolleston believes that his attainment of so advanced an age in full possession of his faculties was mainly due to his practising, with occasional lapses, what he preached.

In all his numerous writings, particularly in his correspondence and in the *Dictionnaire Philosophique,* he refers frequently to the medical profession. While in London where he lived for many years Voltaire became acquainted with Cheselden, one of the best known surgeons of the day, probably with Sir Hans Sloane, president of the Royal College of Physicians and of the Royal Society and founder of the British Museum; with Sir Richard Mead, a physician, a poet and friend of Dr. Johnson and with Freind, one of the earliest medical historians, as well as of several other Fellows of the Royal Society, of which Voltaire was himself elected a member in 1743.

He was a friend and patient of the great Boerhaave of Leyden. Voltaire was at one time an immoderate coffee drinker consuming, it is said, as many as twelve cups a day.

Voltaire, like Herbert Spencer, was very fond of arguing with his medical attendants and too little inclined to carry out their instructions. In matters of public health Voltaire showed the greatest interest. Throughout his life he was an enthusiastic supporter of inoculation against smallpox, which had been introduced by Lady Mary Wortley Montagu into England from Constantinople in 1721.

In one of his letters he refers to the Bishop of Worcester preaching in London, before Parliament, in favor of inoculation, and showing that it saved the lives of two thousand in the capital every year. The prohibition of inoculation by an edict of the French Parliament provoked a bitter protest from him. Voltaire, however, seems to have realized early the principal objection to inoculation, namely, the creation of a fresh source of infection, which was the reason for its prohibition in 1763 by the French Parliament and by the English Parliament in 1840, when its place was taken by vaccination introduced by Jenner in 1796.

In his historical works Voltaire referred to the importance of controlling epidemic diseases, especially plague. He condemned unstintedly the sanitary conditions of the Paris hospitals in which overcrowding and cross infection were the rule, the crowded state of the Paris cemeteries and the practice of burial in churches. He proposed the building of maternity hospitals for unmarried women as a check upon infanticide. Voltaire was one of the first prison reformers and raised his voice in protest against the unsanitary state of contemporary prisons.

1. Interns' home. 2. Superintendent's cottage. 3. Medical building. 4. Library building. 5. Cupola of administration building. 6. Surgical building. 7. Long connecting corridor. 8. Front end of chapel. 9. Medical building, former contagious pavilion. 10. Medical building. 11. Laboratory, dental and clinic building. 12. Medical and children's building. 13. Cross corridor connecting long corridor with service building. 14. Psychopathic department. 15. Garage and morgue. 16. Laundry. 17. Service building, including class rooms, kitchen, diet kitchen, dining rooms, drug room, storeroom, etc. 18. Medical, physiotherapy, and outpatient building. 19. Operating pavilion. 20. Ward building. 21. Communicable diseases building. 22. Leprosarium. 23. Power plant. 24. Bridge connecting Nurses' Home with service building. 25 and 26. Two cottages of the Nurses' Home.

Los Angeles General Hospital*

HARRY S. FIST, Ph.C., B.S., M.D.
Los Angeles

To describe satisfactorily the Los Angeles General Hospital it is necessary to consider several problems which are met with in caring for the large number of sick in a civic hospital serving a population of more than two millions.

The cost to Los Angeles County last year for medical and charitable services amounted to approximately four millions of dollars. Seventy per cent. of the dependency is due primarily to sickness or is complicated by it. If, therefore, a county hospital does not restore its patients to earning capacity, they and their dependents become county charges and constitute an additional expense.

"A county institution should have at least seven kinds of services in order to care for the different types of cases" (1).

1. Visiting nurses and physicians for indigent home patients, whose removal to an institution is unnecessary and unsuitable.

2. A home for the indigent (homeless and aged) where proper care may be given at a per diem cost per bed of about one dollar and fifty cents.

3. A chronic hospital for incurable sufferers from paralysis, arthritis, recurrent cancer, etc., where the cost is relatively low.

4. An institution for the harmless insane.

5. A sanitarium for the tuberculous.

6. A convalescent home costing one dollar and seventy-five cents a day, designed to bring patients to a state of health where they are again productive.

7. A hospital for acute cases—equipped to furnish skillful nursing and the best of modern medical and surgical attention, where nothing is spared in the attempt to furnish the best. The very finest of apparatus and housing must be supplied.

Consultation with experts in any field of medicine must always be available. In such a hospital the per diem cost is five dollars, and the average stay ten to fifteen days. By using every means possible, and so restoring the patient to health much more quickly, a large saving is effected.

At 1100 Mission Road, away from the noise of the city, among the palms which flourish so luxuriantly in the eternal sunshine of California, stands the Los Angeles General Hospital, a monument to modern medical science, and to man's humanity to man.

The normal capacity of 1,283 beds (including bassinets), is at present reduced to 1,150 beds because of rebuilding operations. Arrangements are complete for the erection of a new four million dollar addition, an acute hospital of 1,600 beds. This hospital is to be equipped with the finest of modern appliances for the diagnosis and treatment of disease.

In 1919 the house staff included some ten resident physicians and twenty-five internes. At the present time Dr. Phoebus Berman, the assistant superin-

tendent, has under his direction twenty-seven full-time resident physicians, fifty-eight interns (appointed by examination), and two dentists. The number of patients is practically the same as in 1919, but the type of cases has changed entirely. Not only do many more acutely ill patients receive better care, with sixty new inpatients admitted daily; but a large outpatient department has recently been established under the supervision of Dr. William Kristensen, averaging 432 outpatients daily.

A large and efficient social service department investigates the financial status and home conditions of each patient, thus supplying valuable information with regard to which of the seven types of service is required.

Yearly examinations are held along civil service lines, to determine the fitness of physicians for the staff. Only those who have satisfactorily passed said examinations are appointed. That it is a desirable service is evidenced by the large number of applicants.

The efficiency demanded may be deduced from the fact that all staff members (including the two hundred visiting senior and junior physicians), punch the timeclock on entering and leaving the institution.

The department of internal medicine, headed by Dr. J. V. Barrow, cares for the medical inpatients, of which there were some twelve thousand last year.

In the department of surgery, headed by Dr. J. H. Seymour, F.A.C.S., 4,915 major surgical operations were performed during the past year.

In the obstetrical department, of which Dr. E. M. Lazard, F.A.C.S., is chief, there were delivered 1,399 babies last year. During the past year a noteworthy contribution of this department has been the development of the intravenous use of ten per cent. magnesium sulphate, in the treatment of eclampsia (2). The outpatient maternity service is provided by the City and County Health Departments, under the care of Dr. George Parrish and Dr. J. L. Pomeroy.

With the County Health Department, the General Hospital works in liaison in providing dispensary service for outpatients in the outlying districts of the county, by supplying visiting physicians and nurses.

Thirty-seven thousand five hundred and forty-two radiographs and treatments during the past year, indicate the amount of excellent work done by the x ray department, under the direction of Dr. R. A. Carter.

The malignancy board, composed of Dr. Rex Duncan, Dr. James F. Percy, F.A.C.S., Dr. A. Davidson, and their associates, passes upon every case of malignancy or suspected malignancy admitted to the hospital, thereby making possible a greater reduction in the mortality of this dreaded disease.

Physiotherapy is conducted as a separate department. It includes massage, electrotherapy, thermotherapy, and heliotherapy. Last year this new department cared for four thousand five hundred inpatients and four thousand outpatients. The roof is utilized for heliotherapy, sunshine being available practically the entire year in Los Angeles.

The department of communicable diseases has recently been moved from the old buildings to new and modern quarters. The percentage of cross infections is now very low.

The department of pathology, under the direction of Dr. George D. Maner, performed a total of 707 autopsies last year, which was thirty-one per cent. of the deaths in the hospital. This is a very creditable number for California, where the number of cults is so large, and much credit is due the staff for the enthusiasm and interest which made it possible.

Showing the beautiful grounds and some of the buildings of the institution.

There is a nursing staff of 522, graduates and undergraduates.

In connection with the hospital is the School of Nursing, established in 1895, fully accredited, and requiring for admission a high school education or its equivalent. Last year there was graduated a class of forty-eight nurses.

Monthly meetings are held by the attending staff for the purpose of discussing subjects of medical interest, and all proceedings are published in *The Staff Bulletin*. Many of the papers here presented have appeared later in first class medical journals.

The Los Angeles County Medical Society holds its annual clinic week at this hospital, December 1st.

The faculties of the College of Medical Evangelists and the Post Graduate School of the University of California include many of the staff of this hospital, who use the wards for bedside teaching. All year-'round, the Los Angeles General Hospital welcomes to its "ward walks" medical visitors from all over the world.

News Items.

Prenatal Consultation.—At a recent session of the Academy of Medicine of Fulton, N. Y., prenatal consultations and nursing work connected therewith received unanimous endorsement, and a prenatal consultation unit will be scheduled for Fulton in the near future.

No Accident Day for Children.—This day was celebrated on May Day by the cities of New York, Boston, Washington, Baltimore and San Francisco and was marred by only one fatality, the accidental death in New York of a child. The tallies were kept and tabulated by the police departments of the various cities.

Tuberculosis as a Social Problem.—The University of Michigan will offer from June 21st to July 30th and from June 21st to August 13th a course in work with the tuberculous. Theodore J. Werle and Edith Jane Foster, of the Michigan Tuberculosis Association will supervise the course. The curriculum will include tuberculosis as a social problem and the duties of public health officials, nurses, lay health workers, social workers and club women.

Donation to Cancer Fund.—Announcement was made on May 2d by Winthrop W. Aldrich, in charge of the campaign for a million dollar endowment for the American Society for the Control of Cancer, that John D. Rockefeller, Jr., had made an unconditional gift of $125,000 to the society. He has made also another gift of $10,000 to defray the expenses of a congress of the leading cancer specialists of this country and Europe to be held at Lake Mohonk in September.

A Course in Public Health Legislation at Columbia.—The summer courses at Columbia University will, as for the three past years, include lectures on public health legislation and laws. These will be given from July 6th-16th for one hour daily from one to two p. m. These ten sessions will count as one point and will cost each student $10 as a tuition fee. Persons interested should communicate with the Director of the Summer Session, Columbia University, New York City.

A Course of Lectures on Mental Hygiene.—The National Committee for Mental Hygiene and the Committee on Mental Hygiene of the State Charities Aid Association are planning for next winter a course of lectures on mental hygiene similar to those given on Tuesday afternoons during the past winter at the New York Academy of Medicine. The enrollment for the course was as large as the seating capacity of the auditorium permitted, yet many had to be refused and turned away from the entrance, so great was the interest displayed in the fourteen lectures.

New Regulations for Safeguarding Health of Painters.—Announcement has been made by the Massachusetts State Department of Labor and Industries that new rules for those engaged in the painting business have been adopted. These became effective on January 1, 1926. These regulations concern general safety provisions, requirement for registration, and general health requirements especially intended to provide protection for workmen using spray coating apparatus. Dr. Wade Wright was chairman of a special committee which assisted the Department of Labor and Industries in drawing up the new rules.

Health Activities in Syracuse.—The city of Syracuse, N. Y., has assumed in its budget for 1926 the maintenance of various health activities in the Health Department for which $40,060 was spent in 1925 by the Milbank Memorial Fund, and similarly in the Department of Education school hygiene service for which last year the Fund spent $16,090. The total expenditure made by the fund in 1925 for the Health Department was $72,035, and $20,833 for the Department of Education. The appropriation made from city funds by the city financial authorities for the Health Department for the current year is $224,800, and for the school hygiene service in the Department of Education, $62,500. Much of the credit for this action on the part of the city authorities is due to the recent health demonstration in Cattaraugus County.

A Sedgwick Memorial.—A William Thompson Sedgwick Memorial Lectureship and Medal Fund is being promoted by appropriate committees. Dr. Victor C. Vaughan was the proposer of the memorial. Through it students in public health at the Massachusetts Institute of Technology will every year be enabled to listen to representative authorities in the field of health, and medals will be awarded by the American Public Health Association, custodian of the medal fund, to men who render service in the work. Subscriptions should be sent to the William Thompson Sedgwick Memorial Lectureship and Medal Fund, 370 Seventh Avenue, New York City, addressed to Homer N. Calver, secretary of the medal committee, or to C. E. Turner for the lectureship committee.

Hospital Provisions in New York State.—According to the report of the New York State Board of Charities for the last fiscal year, there are 60 public hospitals in the State, exclusive of those for mental diseases, with a total bed capacity of 17,292. The average daily census was 12,711 or 73.5 per cent. of utilization. The average per capita cost was $3.31.

Reports from 195 private corporate hospitals representing about two thirds of the total number in the State give a bed capacity of 21,865 with an average daily census of 16,706, or 76.4 per cent. The per capita daily cost was $4.75 or $1.44 per day more than the public hospitals. In New York City the per capita cost for private general hospitals was $5.83. County tuberculosis hospitals had an average per capita cost of $2.81.

The lower percentage of utilization of public hospitals is explained by the fact that such institutions made provision for the care of communicable disease cases which are seasonal in their highest incidence.

Personal.—Asst. Surgeon General F. C. Smith, of the U. S. Public Health Service, has recently been in Perry Point, Md., for a conference with the officer in charge of the Supply Depot.

Miss Ella Sandstrom has been given charge of the instruction in occupation therapy of the new bureau recently opened at the Auburn Municipal Sanatorium, Auburn, N. Y. Miss Sandstrom has been a patient for several years in the Chautauqua County Tuberculosis Hospital where she developed efficiency as an occupation therapy aide while convalescing.

Regional Consultant Daisy M. O. Robinson, of the U. S. Public Health Service, attended the recent meeting of the Medical Women's National Association at Dallas, Tex.

Dr. Thomas Parran, Jr., of Raleigh, N. C., has been studying local methods in North Carolina of communicable disease control.

Dr. Emil Krulish, of Ellis Island, N. Y., attended the recent conference at Washington of field officers of the Office of Indian Affairs.

Dr. J. F. Montague, of New York City, recently addressed the Milwaukee Academy of Medicine on the subject of Popular Fallacies Concerning Hemorrhoids.

Dr. Grover A. Kempf, of Washington, D. C., has recently been investigating child hygiene conditions in Maryland.

Surgeon L. R. Thompson, U. S. Public Health Service, has been in Greenville, S. C., in connection with an investigation of respiratory diseases among cotton workers.

Leonard Greenburg, Associate Sanitary Engineer of the U. S. Public Health Service, will go from New Haven, Conn., to Niagara Falls, N. Y., the latter part of the month to study benzol poisoning.

Lieut. G. E. Mott, of the Medical Corps of the U. S. Navy, has devised a "posturegraph," a machine devised to record posture defects, which is described with illustrations in the *Nation's Health* for April.

Miss Helen F. Connally of Troy has been appointed County public health nurse of Schuyler County, N. Y., by the Public Health Committee and the Board of Supervisors of the county.

Society News and Notes.

The Committee of Medical Education of the New York Academy of Medicine and the New York Tuberculosis and Health Association have arranged for a course in cardiology for North Harlem physicians. The sessions began on April 23d and are being held weekly on Friday afternoons. Five sessions will be held at the Harlem Hospital, six at the Presbyterian Hospital, and one at Mt. Sinai Hospital. The program for the remainder of the course is as follows: May 7th, at 2 p. m., at the Presbyterian Hospital, the arrhythmias; the electrocardiograph, by Dr. Archibald M. Strong; May 14th, at 3 p. m., at the Harlem Hospital, the rheumatic heart; mitral stenosis and insufficiency; adherent pericardium, by Dr. Angelo Sala; May 21st, at 2 p. m., at the Presbyterian Hospital, the decompensated rheumatic heart, by Dr. Robert Loeb; May 28th, at 3 p. m., at Harlem Hospital, fibrillation and digitalis, by Dr. Milton B. Rosenbluth; June 4th, at 4 p. m., at Mt. Sinai Hospital, amphitheatre, autopsy room, bacterial endocarditis, by Dr. George Baehr; June 11th, at 3 p. m., at Harlem Hospital, syphilis of the heart; aortitis and aneurysm, by Dr. Thomas A. Martin; June 18th, at 2 p. m., at the Presbyterian Hospital, degenerative heart conditions, by Dr. Martin De Forest Smith; June 25th, at 3 p. m., at the Harlem Hospital, hypertension; blood chemistry, by Dr. Leopold H. Berliner; July 2d, at 2 p. m., at the Presbyterian Hospital, the principles of cardiac therapy, by Dr. Walter P. Anderton; July 8th, at 3 p. m., at Harlem Hospital, drug treatment, by Dr. Lewis K. Neff.

The National Committee for the Prevention of Blindness has announced that the Leslie Dana Medal for the most outstanding achievement in the prevention of blindness will be awarded this year to Miss Louise Lee Schuyler, of New York City. In 1908 Miss Schuyler launched a movement to combat preventable blindness, and under her leadership many health and educational agencies cooperated to bring about in almost every state legislation prescribing treatment by doctors, midwives and nurses of the eyes of newborn children, the most common source of blindness in later years. This movement grew to include the prevention of blindness from all causes. Miss Schuyler was responsible for the founding of the National Committee for the Prevention of Blindness.

The Brooklyn Urological Society has recently elected the following officers: President, Dr. Samuel Parnass; vice-president, Dr. Albert Harris; secretary-treasurer, Dr. A. Ravich.

* * *

The last spring meeting of Caduceus Post, American Legion, is being held on the evening of Wednesday, May 19th, at the New York Athletic Club. Dr. John F. Connors and Dr. Harlow Brooks will both speak on their recent hunting trips.

* * *

The American Association for Medical Progress distributed a memorandum of the life and work of Dr. Edward Jenner, with a bibliography and a series of suggestions for public observance of the one hundred and thirtieth anniversary of Jenner's first vaccination, on May 14th.

* * *

The American Psychiatric Association will meet in New York City, June 9th-12th, with headquarters at the Waldorf-Astoria. The finance committee requests that all interested in psychiatry will contribute to the fund for the entertainment of the members at that time. Checks may be mailed to Dr. C. C. Burlingame, 17 East Forty-second Street, New York City.

* * *

The Educational Foundation of the Committee for Relief in Belgium has appointed Dr. Frederick P. Gay, professor of bacteriology at Columbia University, to spend next year in giving lectures on immunology at the universities of Brussels, Liège, Ghent and Louvain.

* * *

The New York Academy of Medicine announces that, commencing June 15th, the Library will be closed at 5 p. m. It will probably be closed all day to readers, from July 15th until September 15th, while the collection is being moved into the new building.

The New York State Charities Aid Association's State Committee on Tuberculosis and Public Health will hold its annual convention of state and local committees at Olean, Cattaraugus County, N. Y., June 1st-3d. Cattaraugus County is the centre of the rural county health demonstration, undertaken with the advice and financial assistance of the Milbank Memorial Fund. Sir Arthur Newsholme, M.D., K.C.B., will address the convention on the first day. During the three days of the meeting, delegates in attendance will be conducted to all parts of the county to see at first hand the work of the three local operating agencies in the health demonstration—the County Board of Health, the county wide School Hygiene District, and the Tuberculosis and Public Health Association. One of the features of the conference will be a visit to the Alleghany State Park where the children's health camp of the Cattaraugus County Tuberculosis and Public Health Association is located.

* * *

The second annual meeting of health education directors of state and local tuberculosis associations is being held at Atlantic City, May 17th-19th, with headquarters for the staff at the Malboro-Blenheim Hotel. The program includes standards for school health service and how tuberculosis associations may help to develop them; problems of rural school sanitation and how tuberculosis associations may help to solve them; a practical plan of cooperation between agencies fostering nutrition work; types of service which tuberculosis associations may give to teachers; a session on teacher training is planned to be held jointly with the division of health education of the American Child Health Association. Small group conferences on special subjects have been arranged.

* * *

One of the features of the American Health Congress being held in Atlantic City, May 17th-22nd, is a pageant on child health, the purpose of which is to symbolize the purpose of the congress, namely, the closer understanding and cooperation between the sixteen national organiaztions comprising the National Health Council. The pageant committee that has developed the plans was appointed by Dr. A. J. Lanza of the National Health Council. The scenery and costumes have been designed and made by the children participating in the pageant.

* * *

Miss Mabel T. Boardman, secretary of the memorial fund committee of the American Red Cross, recently addressed a large assemblage in New York City, in the interest of the proposed women's war memorial in Washington for which Congress has appropriated $150,000. Miss Boardman demonstrated by plans that the new building is to have a laboratory, demonstration station, and a school of chapter activities. She explained how large numbers of volunteers from all parts of the country might be trained to render services that could be utilized by their own communities when not required for Red Cross work.

* * *

Heredity as a factor in public health was discussed in a lecture given recently in London by Dr. Redcliffe N. Salaman, under the auspices of the Jewish Health Organization of Great Britain. He said that a mental defective who lived to be fifty and is cared for by the state could not cost less than five thousand pounds sterling. Sterilization of mental defectives or segregation of these individuals for life seems too drastic remedies to many, but without such legislation not much can be accomplished. Parents of children deficient in any way should do their utmost to prevent them from marrying. In Jewish circles marriage has been considered with such veneration that even degenerates have been forced into marriage, and it is to this fact that their group owes its many defectives.—*Lancet.*

* * *

The Blind Relief Association of India, with headquarters at 65 Kalbadevi Road, Bombay, has sent out an appeal, with descriptive literature, for assistance in maintaining its work, the field of which has become so extended that available funds are far from adequate to finance even a small part of the work. The report emphasizes the large number of the blind in India whose condition could easily have been prevented by the proper measures, and the necessity of reaching the vast numbers of the poor, the ignorant and the superstitious through popular education in personal hygiene, as well as through medical and surgical relief.

Book Reviews

TESTS FOR LIVER FUNCTION

L'Exploration fonctionelle du foie et l'Insuffisance hépatique. Par Noël Fiessinger et Henry Walter. Paris: Masson et Cie, 1925.

Feissinger and Walter first give a detailed description of all the functional tests for the liver, and then show how useful some of these tests are for the clinic. The authors point out that up to recently the secretion of the liver (bile) could be examined merely in its changed form, as it is found in the stool. The duodenal tube made it possible to obtain the bile from the duodenum in pretty pure form, which marks a great advance. Next to the examination of the bile, the most important practical test is the urobilinogen in the urine, as evidenced by Ehrlich's test. For the presence of urobilinogen in marked amounts in the urine always indicates an insufficient functioning of the liver.

With regard to jaundice the authors consider catarrhal icterus as always due to an impairment of the liver cell, which becomes fissured and permits the bile to enter the general circulation. They do not accept the old theory of mucous plugs obturating the biliary canals.

The present book can be considered as one of the best treatises of the liver and is herewith recommended as such to the medical profession.

UROLOGY

Young's Practice of Urology. Based on a study of 12,500 cases. By Hugh H. Young, M.D., and David M. Davis, M.D., Johns Hopkins University. With the Collaboration of Franklin P. Johnson. Two Volumes. With 1003 Illustrations, Twenty Being Color Plates, by William P. Didusch. Philadelphia and London: W. B. Saunders Company, 1926. Pp. 1484.

The authors have produced a work of unusual character and great value. Based on twelve thousand five hundred urological cases, carefully studied and checked up with much effort, we have a vast fund of urological information built up largely upon the personal experiences and inventions of the principal author and his staff.

Particular emphasis naturally is laid on this phase of the subject. Much space is devoted to an elaborate study of the new germicides, mercurochrome and meroxyl; the intravenous administration of antiseptic dyes in general infections; the development of a possible *therapia sterilisans magna;* Young's instruments and his many surgical procedures, many of which have become standard. All of this not only is to be expected from so versatile a surgeon as Young, but it is to be commended, for it gives us a fairly complete picture of his manysided and often ingenious activities in the field of urology.

The first volume is devoted to obstructive uropathy, urogenital infections, urolithiasis, hypertrophy of the prostate and urogenital neoplasms; the second volume considers malformations, traumatisms, operative surgery of the urogenital tract, and miscellaneous allied topics.

The work may be said to be cyclopedic in character. To review these two large volumes within the customary limitations of time and space, would be an almost impossible task. The most that one can say is that the author and his assistants have covered the subject of urology in a masterful manner after a prodigious amount of labor. If any criticism justly can be applied to the work, one might say that it is altogether too comprehensive for the general practitioner, because there is too much in it. Its great merit is at the same time its worst and only fault. Works of this kind serve a mighty purpose as an aid to the profound student of urology; as such, it is perhaps the best work of its kind that has come to our notice.

The illustrations, more than one thousand in number, are skilfully and beautifully done, many of them being original. Typographically the volumes are all that could be desired. Authors and publishers have combined to produce a monumental work, a fine tribute to the high plane achieved by American urologists.

PERTUSSIS

La Coqueluche. Par Dr. Henri Stévenin, médecin des Hôpitaux de Paris. Bibliothèque des Connaissances Médicales dirigée par le Docteur Apert. Paris: Ernest Flammarion, 1926.

This little volume of the Apera series is intended to present, in terms intelligible to the lay public, our present knowledge of the symptoms and treatment of pertussis which, as Stévenin remarks, is so characteristic a disease that the diagnosis is often made without recourse to a physician. Its high contagiosity, long duration, and distressing symptoms, too, are well known. Recent discoveries in the domain of bacteriology, immunization, and serotherapy have changed our viewpoint of treatment. All this is taken into consideration. There are interesting chapters on hygiene and prophylaxis, the question of open air treatment, complications and sequelæ and their prevention. One might note, in passing, that no mention is made of the tracheal injection treatment, of antipyrin, and that the American contributions to this important subject are practically ignored.

PREVENTIVE MEDICINE

Disease Prevention. By Herbert H. Waite, M.D., Professor of Bacteriology and Pathology, University of Nebraska. New York: Thomas Y. Crowell Company, 1926. Pp. 667.

The author states in his preface that it is not his intention to make this book an exhaustive monograph, but a digest written especially for all those who have neither a medical nor an engineering background, and who would, therefore, have some difficulty in securing information from original sources. He adds that the book is primarily intended for social workers, state and municipal officials, hospital workers, and all those who are engaged in the highly laudable work of combating disease. The headings of the twenty chapters show how thoroughly he has covered his subject; these are: Introductory and Historical, the Scope of Sanitary Science, Epidemiology, General Methods of Disease Prevention, Prevention of Diseases Spread Largely Through the Intestinal Tract, Diseases Transmitted Through the Respiratory Tract, Prevention of Diseases of Man Contracted Through Association With the Higher Animals, Diseases Caused by Animal Parasites, Prevention of In-

sect Borne Diseases, Prevention of Venereal Diseases, Prevention of Diseases Conveyed Through Milk and Other Foods, Prevention of Food Infections and Intoxications, Prevention of Water Borne Diseases, Prevention of Soil Borne Diseases, Miscellaneous Communicable Diseases of Uncertain Cause or Mode of Transmission, Prevention of Diseases Due to Industrial or Occupational Hazards, The Public Health Nurse as a Means of Preventing Disease, Measures for the Prevention of Infant Mortality, Value of School Inspection as a Means of Controlling and Preventing Disease, and Prevention of Diseases Transmitted by Parents to Their Offspring. A list of selected references follows the text.

A good deal of clinical material is included in order to give the readers some insight into the varied manifestations of the diseases discussed. The author states that he has given more space to the consideration of diseases caused by animal parasites than is usually devoted to them in a work of this character, because they are more common than is generally believed, and might be avoided by preventive measures. Procedures which have been tried and so established as valuable, are emphasized—in fact, the emphasis is laid throughout on established facts rather than upon theories, although due consideration is given to procedures which, although in the experimental stage, promise to be of future value.

STUDIES FROM THE UNIVERSITY OF HELSINGFORS

Arbeiten aus dem Pathologischen Institut der Universität Helsingfors (Finland). Begründet von Prof. emer. Dr. E. A. Homén. Herausgegeben von Prof. Dr. Axel Wallgren. Neue Folge. Vierter Band, Erstes und zweites Heft. Mit 18 Abbildungen im Text. Jena: Verlag von Gustav Fischer, 1926. Pp. 226.

Three monographs are included in this number of the Studies from the Pathological Institute of the University of Helsingfors. Arno Saxén contributes Pathological and Clinical Studies on the Primary Papillomas and Carcinomas Originating in the Nasal Cavity and the Adjacent Accessory Sinuses. He divides the carcinomas into papillary carcinoma, keratoid carcinoma, basal celled carcinoma, solid cylindrical celled carcinoma, and medullary carcinoma, and discusses the histological appearance and characteristics of each form separately. Round cell infiltration is especially emphasized. The clinical study is divided into two portions: 1, symptomatology and diagnosis, and 2, treatment and prognosis. Sixty-one case histories are also included, as is also a very extensive bibliography.

Dora von Wendt's contribution is Bacteriology of Peritonitides from Ulcer; A Clinical Bacteriological Study. She concludes that the bacterial flora of the ulcer peritonitides may be characterized as a reduced and somewhat modified flora of the mouth. The number of the bacteria is generally fairly unimportant, and the types found are usually of low virulence. The predominant bacteria are nonhemolytic streptococci. Anaerobes are of secondary importance. The prognosis is not made much easier by bacteriologic studies.

The Diagnosis of Amyloid Disease of the Conjunctiva is the work of Ivar Wallgren and Mauno Vannas. They show that the connective tissue is not destroyed nor does it disappear when the amyloid is deposited around it. Furthermore, it appears that the connective tissue proliferates at sites where the amyloid appears in the tissue.

MEDICAL ANNALS

Annales de Dermatologie et de Syphilographie. Fondées par A. Doyon. VI Serie. Tome Vi. No. 12. December, 1925. Paris: Masson et Cie, 1925.

This number contains a complete and fairly detailed report of the Conference on Hereditary Syphilis held at Paris in October of last year. There are, in addition, a number of highly interesting and instructive original articles, notably a continuation by Thibierge of his *Dermatological Lessons of the War,* 1914-1918. Dujardin and Decamps discuss the combined action, in dermatology, of anaphylaxis and "pexic" actions, by which they understand the property of certain tissues, particularly that of the liver, to fix proteins or antigens. Dracoulides of Athens has a short but suggestive note on the "female moustache" as a stigma of hereditary syphilis. He brings it into connection with a state of hyperadrenalism, due to a relative lack of ovarian hormone, which latter is caused by previous luetic damage to the gonad.

Annals of Otology, Rhinology and Laryngology. Founded by James Pleasant Parker. H. W. Loeb, M.D., Editor in Chief. Vol. XXXIV, No. 4. St. Louis, Mo., December, 1925.

Among the society proceedings reported at length, we find that of the Chicago Laryngological and Otological Society of April 6th, and the annual meeting of the American Otological Society. Among the original articles are interesting presentations by Jones and Knudsen on Facts of Audition [they are just as much facts of acoustics], by Hammond, of Boston, on Hearing Results in Radical Mastoid Operations, and by Fenton on Vaccines from Hemolytic Cocci in Sphenoethmoidal Disease. Eves has an instructive paper on the Diagnosis of Lateral Sinus Thrombosis, and Morse discusses the prophylaxis and treatment of repeated coryzas. The ophthalmologist will be interested in Gittin's case reports of orbital cellulitis complicating paranasal sinus disease in children.

Medicoliterary Notes.

Midwifery Supervision Succeeds in New Jersey is the title of an interesting article in the April issue of the *Nation's Health* by Dr. Henry B. Costill, director of the New Jersey State Department of Health.

* * *

The *Survey Graphic* for April contains a series of pictures illustrating diphtheria immunization taken in Syracuse and Cattaraugus County, N. Y., by Louis W. Hine. The photographs are prefaced by a brief summary of the purposes of the recent state wide campaign against diphtheria.

* * *

E. H. Lewinski Corwin, Ph.D., director of the Hospital Information Bureau of the United Hospital Fund of New York, has an interesting article in the issue for April 2d of *Public Health Reports* on the Community Responsibility of Hospitals.

* * *

A general child welfare clinic has been opened in the pediatric department of the University of Virginia Hospital, the work to include the teaching of pediatrics to nurses and medical students, and general human welfare. One of the objects of the new clinic is to reach the children of the moun-

tain folk of the western part of the State of Virginia. In cooperation with the department of psychology of the university, psychological tests will be made of the children and their parents, and, with the department of anatomy and anthropology, observations will be made of nationality and race characteristics.

* * *

The *Forum* for February contains an article by E. E. Free on the measurements recently made by him of New York's noises. A map has been drawn up, showing the city's silent places—if any—the differences between day and night sounds, and day and night stillnesses, and the results related to the life and habits of neighborhoods in terms of traffic, sound distribution, and other agencies during day and night. This has led to the derivation of a "noise level," in other words, the average noise intensity of the city has been determined on the basis of the sound measurements made. The work was done with a view to creating an authoritative basis for attempting to remedy noise nuisances prevailing in such a degree as to make certain localities undesirable for residence purposes.

* * *

Two recent publications of interest from Henry Holt & Company are the *Game of Love and Death,* by Romain Rolland, one play of the series of twelve upon which he is working, based upon the events of the French Revolution, and planned to reveal the resistless force of elemental passions upon faith, patriotism and the social instinct; and William Beebe's new book, the *Log of the Sun.* The latter is one of Beebe's early works, and is reproduced with the original full color illustrations.

* * *

According to a recent report of the Joint Committee on Methods of Preventing Delinquency, the cities of St. Louis, Dallas, Minneapolis, St. Paul, Los Angeles, Memphis and Richmond now support child guidance clinics. At these clinics problem children are given systematic physical, psychological and psychiatric examinations, and are helped by trained workers to try to adjust themselves to more normal habits of life.

* * *

The Illinois *Institution Quarterly* has been superseded by the *Welfare Magazine,* which made its first appearance in January, 1926. This issue contains the proceedings of the fifth annual Illinois Conference on Public Welfare held at Urbana in October, 1925.

* * *

Curing the Criminal is the title of a recent publication of the Macmillan Company by J. O. Stutsman, general superintendent of Rockview Penitentiary, Pennsylvania. The book discusses in a sane and unsentimental manner the evolution of humane methods, the transition of prison architecture, "prisons without walls," prison industries and compensation of prisoners, maintaining discipline in prison, the value of recreation for prisoners, self government of prisoners, the police as a deterrent agency, socializing the court, the death penalty, "probation or jail," and parole.

* * *

The Louisiana State Board of Health has issued its *Almanac* for 1926, gay and attractive in a bright cover, and full of good advice on health subjects, public and personal. It is illustrated with good line drawings and neatly and attractively printed.

* * *

An interesting and valuable report published in the *American Journal of Public Health* for March is that of the Committee on Mosquito Control presented to the Sanitary Engineering Section of the American Public Health Association at the fifty fourth annual meeting last October.

* * *

The Williams & Wilkins Company, publishers of Baltimore, have announced the publication of the first series for 1924-25 of the *Dohme Memorial Lectures* given each year at Johns Hopkins University for the purpose of promoting the development of closer relationship between chemistry, pharmacy and medicine. The volume of lectures for 1924-25 is bound in two ways—cloth and paper, the latter form at a considerably lower price, suitable for the student. The lectures are by leading authorities, among them Dr. Stieglitz and Dr. Cushny.

* * *

The Health Organization of the League of Nations has recently issued a valuable monograph on the Public Health Services in Australia, by Dr. J. H. L. Cumpston, director of general health of the Commonwealth of Australia, and Dr. Frank McCallum.

* * *

Recent annual reports of interest are those of the Lenox Hill Hospital, New York City, the Boston City Hospital, and the New York State Veterinary College at Cornell University.

* * *

Articles of interest in recent issues of the *World's Health* are How the Belgian Red Cross Met the Floods, by Dr. René Sand; The Russell Sage Foundation, by John M. Glenn; and Prevention of Accidents by Educational Methods, by Arthur Williams, general commercial manager of the New York Edison Company and president of the American Museum of Safety, all in the March number; and the seventh of the series of articles covering present day civil and humanitarian activities of the aeroplane, Aerial Medicine and Teaching, by H. C. Loeffler, of the relief division of the League of Red Cross Societies. in the April issue.

* * *

From a child's examination paper—The five senses are sneezing, sobbing, crying, yawning and coughing. By the sixth sense is meant an extra one which some folks have. This is snoring.—*Bulletin of the Chicago Municipal Tuberculosis Sanitarium.*

* * *

The leading article in the *Weekly Bulletin* for April 10th of the Department of Health of the City of New York is On Quacks and Quackery, which is concluded as follows: "The Department of Health is cognizant of the multiplicity of phases in the quackery problem, and seeks to achieve its elmination both through the exercise of police power and the spread of education. The Division of Illegal Medicine is charged with the detection, investigation, and facilitation in prosecution, by the District Attorneys' offices of quacks and illegal practitioners. The Bureau of Health Education, through popular lectures, literature, posters, and the radio, is carrying on the educational part of the war on quackery. All signs point to the achievement of desirable results, and it is not an over sanguine expectation to have New York City substantially freed of its quacks, within a short time."

* * *

Influenza, thus far this year, has by all accounts been very prevalent and a source of serious disability and absence from school work. The form of the disease, however, has not been generally virulent. This is best indicated by the mortality experience among the 17,000,000 industrial policy holders of the Metropolitan. While the death rates for both influenza and pneumonia have run higher, so far this year, than last year, the mortality figure for neither disease is unusually high as compared with other recent years.—*Statistical Bulletin, Metropolitan Life Insurance Company.*

* * *

The July issue of *Medical Life* will be devoted entirely to the History of Stomatology by Dr. A. J. Asgis, of New York. The issue will be profusely illustrated. There will also be a chapter by E. B. Hardisty on Stomatological Education in the United States in 1926.

* * *

A Vienna specialist has recently told us that our ears are growing larger and larger because of the din of life in cities; now the dean of the College of Dentistry of the University of Iowa tells us that, because of soft food and little chewing, we are becoming weak jawed. Dr. Breene said that the advantage of the Eskimos lies in their raw meat and other food difficult to chew, but he did not advocate literal imitation by the American public—only an endeavor through education to check the growing tendency toward the eating of soft foods.

American Medical Association

Seventy-seventh Annual Meeting, Dallas, Texas, April 19-23, 1926

(*Continued from page 629*)

The Scientific Proceedings

We present below abstracts of some of the more important papers read at the various section meetings. The publication of these abstracts will be continued in future issues of the JOURNAL.

SECTION ON DISEASES OF CHILDREN

CHAIRMAN, DR. CLIFFORD G. GRULEE, OF CHICAGO.
SECRETARY, DR. HUGH MC CULLOCH, OF ST. LOUIS.

The Breast Feeding Demonstration and the Practising Physician.—Dr. Frank Howard Richardson, of Brooklyn, said that hand in hand with the reawakening of interest in breast feeding had gone a new development in social medicine—the breast feeding demonstration. The two cardinal principles for universalizing breast feeding were completely emptying the breast, and completing the baby's feeding by giving him as much as he wants of a completing or complementary feeding. He said that the three essentials for conducting a breast feeding demonstration in a community were, 1, an interested and informed group of doctors; 2, the birth recording bureau of the health department; and 3, a body of nurses for visiting newly made mothers to instruct them in accordance with the doctors' orders, how to nurse their babies

It had been a very easy matter to get brilliant results as long as the demonstration was in force, wherever put on. But the results in the years following the termination of organized effort had been disappointing. The reason for this seemed to have been that the doctors as a body had not become acquainted with the details of the work, so that they would and could carry it out in their own practices. In an effort to overcome this, the Nassau County, Long Island, Demonstration had established a rule that no nurse should call upon any mother without obtaining the consent and the instructions of the doctor who had signed the birth certificate. This did away with much of the opposition encountered elsewhere. In the "daughter demonstrations" put on in various parts of New York State, a second step had been taken, in that in every case the demonstration was put on only in response to a definite invitation extended by the local unit of organized medicine.

There remained a third step to be taken, and the success of the breast feeding demonstration was assured. This step was now being urged, in the case of two of the largest cities that were considering initiating such demonstrations. It consisted of bringing before the members of the local medical organization the whole subject of breast feeding, as part of the graduate medical education movement now sweeping over the country. In this way the technic of breast feeding, its almost universal applicability in the hands of men who understood this technic, its possibilities, its advantages, as well as difficulties, all became matter of common knowledge to the men who must eventually carry on the work in their own community, if it was to be carried on at all. Such teaching must be clinical as well as didactic. Most important of all was the fact that the teaching was offered by the physicians' own organization, and not by any outside agency, no matter how well meaning. Doctors are usually eager for graduate education; but they want to initiate their own betterment, and they object to "being done good to!"

Dr. Richardson said that this teaching was now in contemplation by one of our largest cities, as a component part, possibly a preliminary part, of its projected breast feeding demonstration. This should mean even better figures for future years, than those obtained during the artificially stimulated years of the demonstration itself. In no other way could the results of such a demonstration become permanent.

Sporadic Meningococcus Meningitis.—The Sequelæ Following Specific Serum Therapy in Infancy and Early Childhood.—Dr. Stafford McLean and Dr. John P. Caffey, of New York, reported the followup observations in forty-four cases. The curative value of specific serum in the teratment of sporadic meningococcus meningitis in infancy and early childhood had been evident for many years, they said. Prior to the introduction of serum therapy the mortality of the disease in the first year of life approached one hundred per cent. Approximately fifty per cent. of the patients under one year of age treated by them with serum, recovered. In children between the ages of one to five years, eighty-five per cent. recovered. The later growth and development of these children with apparent complete recovery from their acute infection was of interest and of considerable importance. The authors had observed forty-four such cases (excepting two patients who died in the first year after discharge from hospital) over a period varying from one to ten years, and these formed the basis of their report.

In ninety-seven cases of meningococcus meningitis treated with serum at the Babies' Hospital in the ten year period from 1916 to 1926, recovery occurred in fifty-nine, or sixty-one per cent. These cases were all of the sporadic type since the disease had not appeared in epidemic form in New York City in the period covered in this study.

SUMMARY

1. Forty-four cases of sporadic meningococcus meningitis in patients from thirty-five days to four and a half years of age, treated with antimeningococcus serum were followed from one to ten years after treatment.

2. The following serious sequelæ developed in nine of the cases: deaf mutism in four cases, hydrocephalus in two cases, visual impairment in two cases, and mental deficiency in one case.

3. Five patients died during the period of observation.

4. Thirty were alive and normal in every respect at the time of writing.

5. In eleven cases in which serum was injected into the ventricles and cisterna magna because of obstruction of the subarachnoid space, eight patients made complete permanent recovery.

SECTION ON ORTHOPEDIC SURGERY

CHAIRMAN, DR. FRANK R. OBER, OF BOSTON.
SECRETARY, DR. JAMES A. O'REILLY, OF ST. LOUIS.

Some Diagnostic Problems Presented by the Hip in Early Life.—Dr. J. Albert Key, of St. Louis, Mo., said that many hip conditions were treated over long periods without a correct diagnosis. The results obtainable by the various diagnostic procedures were briefly discussed. He emphasized that various pathological conditions in the hip might result in similar clinical pictures. The fact that certain conditions tended to occur in definite age periods was to be considered as an aid in diagnosis.

Obscure cases were presented; 1, lesion of the acetabulum resembling Legg's disease; 2, lesion in the head of the femur of unknown origin; 3, obscure nonarticular arthritis; 4, pyogenic infection in the neck of the femur; 5, tuberculosis of the hip.

The Preoperative Differential Diagnosis of Bone Tumors.—Dr. Henry W. Meyerding, of Rochester, Minn., called attention to the necessity for a clear conception of the types of bone tumors and certain fundamental data, such as the history, clinical examination and properly prepared röntgenogram, in differentiating inflammation and benign and malignant bone tumors. The most important question to the physician, he said, was the distinction between the malignant and the benign. There were certain inflammatory conditions, due to trauma, syphilis or other infection, which must be excluded before the presence of a bone tumor could be determined.

The presence of a bone tumor, growing primarily in bone, having been determined differentiation between such tumors and metastatic lesions, must be considered. Both benign and malignant bone tumors may occur either locally or generally. In most cases of benign tumor there is usually a history of prolonged mild pain, sometimes with fracture or deformity, and the patients often work up to the time of consultation. On the other hand, the malignant tumors progress rapidly in extent and severity of symptoms. A history of previous illness, with pyrexia, pain, and so forth, suggesting an infection, or a history of syphilis, may be a guide to the nature of the lesion. The benign lesions such as osteofibrosa cystica, exostosis and osteoma occur for the most part in the young.

Multiple swellings in the ribs, sternum, clavicle and skull always suggest myeloma. Bending and thickening of the bone in the young suggest osteitis fibrosa cystica; soft, pulsating tumors in the region of the joints are usually giant cell tumors. Chondroma may show little or no local findings. Joint function is rarely impaired until late, in the cases of benign tumor. Periarticular and periosseous involvement is commonly seen in cases of malignant tumor and produces a fixed massive tumor of the soft tissues; the soft tissues are rarely involved in the benign lesions. On the other hand, inflammatory lesions may involve the soft tissues, but usually the severe pain, local heat, pyrexia and leukocytosis combined with the history of acute onset, will differentiate these from the malignant tumors.

Considerable stress was laid on the röntgenographic findings in differentiation, and the author believes that with the proper preparation and interpretation of röntgenograms almost all bone tumors may be correctly diagnosed. The knowledge gained from the röntgenogram as to the origin of the growth, the condition of the cortex and periosteum, the relation of the tumor to the epiphysis and diaphysis, and its osteolytic and osteoplastic character has an important bearing on the differential diagnosis. Such interpretation demands expert opinion, which the average physician seldom has an opportunity to acquire on account of the rarity of these tumors. The preoperative laboratory tests have been of little value, with the exception of the finding of Bence-Jones protein in cases of multiple myeloma, and the demonstration of the severe secondary anemia which accompanies rapidly growing malignant tumors. The röntgenogram provides the earliest evidence of pulmonary metastasis, and the author advises röntgenograms of the lungs in all cases of suspected malignant disease.

The differential diagnosis of bone tumors demands cooperation among the physician, surgeon and röntgenologist when differences of opinion arise. The value of the pathologic examination, both macroscopically and microscopically, should not be forgotten inasmuch as the fate of the extremity may depend on it.

SECTION ON PRACTICE OF MEDICINE

CHAIRMAN, DR. E. S. KILGORE, OF SAN FRANCISCO.
SECRETARY, DR. BRYCE W. FONTAINE, OF MEMPHIS.

Etiology and Treatment of Pernicious Anemia.—Dr. Lewellys F. Barker, of Baltimore, said that though it was true that the cause of pernicious anemia was unknown and that no cure had yet been found for the disease, these statements if unqualified would be very misleading. Much progress had been made toward gaining an understanding of what the causes of the disease must be and of what the links in the pathogenetic chain most probably consisted.

A careful consideration of the large number of facts available now regarding the disease gives certain clues to etiology. Pernicious anemia is peculiar in its incidence and distribution, in the time of life at which it appears, in the form of blood destruction that occurs, in the peculiar form of bone marrow response to the anemia during regeneration, in the frequent association of the anemia with achylia gastrica, with combined sclerosis of the spinal cord, with certain endocrine features, and with a certain type of bodily configuration. It is also remarkable because of its periodical course with tendency to spontaneous remissions and exacerbations. Finally, it is a fatal disease despite the most diligent and skilful treatment.

Many hypotheses of etiology have been advanced. At present the evidence favors an hereditary predisposition as the main cause though various influences

in the environment, particularly poisonings of various sorts are to be regarded as accessory, releasing or provocative factors.

Though physicians cannot cure the disease therapy is far from being unrewarded. By means of rest, the administration of dilute hydrochloric acid and of arsenical preparations, blood transfusions, and other measures, the patient's condition can often be greatly improved and frequently remissions of longer or shorter duration are thus obtained.

The fact that the disease remains latent until middle or later life in most persons predisposed to it, gives rise to the hope that this latency may, in many instances, be prolonged by special attention to hygienic measures in members of families that are susceptible. Thus early recognition of achylia gastrica, of slight paresthesias in the fingers and toes, of a tendency to sore mouth and of certain changes in the blood before anemia actually develops, may permit of the institution of a régime which will help to keep the malady from manifestation for a longer time. If it is true that a hereditary factor is the main cause, intermarriage of members of families in which the disease is known to occur should obviously be discouraged.

SECTION ON SURGERY, GENERAL AND ABDOMINAL

CHAIRMAN, DR. DALLAS B. PHEMISTER, OF CHICAGO.
SECRETARY, DR. J. TATE MASON, OF SEATTLE.

The Surgical Treatment of Cleft Palate.—Dr. George V. I. Brown, of Milwaukee, Wisconsin, described as follows a new method for the surgical treatment of cleft palate which he said was primarily a reconstructive application of parts of many old operative procedures revised to form what was in effect a new operation.

The Von Langenbeck-Warren mucoperiosteal flap operations have rendered great service in the correction of cleft palate during many years as applied by surgeons in this and other countries. Nevertheless, there are certain important objections to operations of this type which long experience has taught us that it would be greatly advantageous to overcome.

According to the new procedure, bone is included in the tissue flaps. The plentiful blood supply from the intranasal vessels is not interfered with, and complete union is favored to that extent. The attachments of the levator and tensor palati muscles with the fibrous tissue at the border of the hard palate are not dissected free, therefore scar contraction and stiffening, as well as shortening of the velum, are correspondingly avoided. There is no compression of the maxillæ, therefore, nasal and oral development are not disturbed. The speech results seem to be better because the anatomical relation of nasal and palatal structures are more correct, and speech training correspondingly less indispensable.

Certain elementary principles pertaining to the treatment of harelip are indispensable to a proper consideration of the surgical character of cleft palate because upon the manner in which the lip is treated will depend in a large measure the character of the palate fissure, even though nothing be done to the palate directly at the time. In other words, the operation to close the lip defect should influence the future operative conditions favorably by making each step of the necessary correction easier and not more difficult as so often occurs.

The association of malformations and malpositions of the premaxilla, the alar cartilages, the nasal septum, the vestibulæ, and other cartilaginous nasal structures in cases of third degree harelip and cleft palate require that they be given immediate corrective attention when the lip fissure is closed. This should be done with the least possible forcible replacement of the premaxilla beyond the actual necessary requirements to permit satisfactory approximation of the lip borders. No compression of the sides of the palate should be applied to force the fissure borders into contact, and even the fixation of the premaxilla by sutures after forcing it into position should be avoided if possible.

Traumatic injury of this character may injure or destroy developing teeth. There is abundant evidence of the permanent disadvantages to health, to the upper dental arch, facial appearance and other undesirable conditions due to forcible narrowing of the bony walls of the palate by immediate compression of the alveolar outline of the mouth.

The order of procedure that I have followed for many years is to operate for closure of harelip with simultaneous reconstruction of the deformed nose in such manner as to assure nasal breathing, improve the appearance of the alar outline, straighten the lower border of the nasal septum, and give correct alignment of the lip muscles, as soon after birth as the condition of the child and other governing factors will permit. At six to eight or nine months old the first step palate operation is performed and one year later the final operation makes the parts complete before wrong speech habits have become established.

The change now recommended is that instead of closing the anterior part of the palate fissure at the first step operation as formerly, I reverse the order and close the velum and posterior part of the hard palate at the first step. Instead of a mucoperiosteal flap operation according to a modification of the Von Langenbeck method which I have previously employed I now include bone segments with the flaps as in the Ferguson operation, but without the serious objections to that method that it seemed advisable to overcome.

The ideal cleft palate operation then must be one that will not deform the mouth, but will give the utmost blood nourishment to the flaps, the least possible shortening of the velum, a minimum of velar rigidity from scar formation, and a maximum rigidity at the posterior border of the hard palate to permit better function of its attached muscles. The bone flap operation is not favorable for the closure of the velum in which the bone is not involved. In such cases the Von Langenbeck-Warren types of procedure are indicated.

In performing the bone flap operation according to the new plan, incisions are made on both sides of the palate in anteroposterior direction along the line of and just inside the alveolar ridge in edentulous infant cases and if teeth have been erupted, just sufficiently away from the linguogingival border to prevent injury to tooth roots. A chisel is forced directly through the external hard surface of the fragmentary

palatal bone structures into the cancellous structure and then inclined toward the palatal fissure border. The palatal bone between the incision and the fissure on each side is fractured, the blood controlled by gauze packing and a loop suture of double silk worm gut is passed completely around the divided segments on both sides and when drawn tight the fissure border is brought in contact without difficulty throughout the entire length of the velum well up toward the center of the hard palate. The borders are freshened, but the entire part of the palate is not closed at this time.

One year later a mucoperiosteal operation is done to complete the fissure closure. The advantages of this method are that there is less danger of loss of tissue and imperfect result along the central line because of the unrestricted blood supply and the palate closure is complete before speech habits have become fixed. There is as nearly as practicable a full length velum which is not stiffened by scar contraction and a posterior border of the palatal bones that is favorable to natural physiological function of the attached muscles. No serious injury is done to the alveolar outline, or to the premaxilla, or the erupting teeth contained therein. Therefore the nares have not been unduly contracted and natural respiratory activity will assist in improving the muscle outline.

There will be a better appearance to the lip because of the eruption of teeth in nearly or quite normal position and the activity of the palatal and pharyngeal muscles cooperating with labial and facial muscles will assist development that must favor improving progress toward more symmetrical facial and labial outlines, and all of the foregoing advantages naturally lend themselves to the acquirement of better speech.

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY

CHAIRMAN, DR. GEORGE GRAY WARD, OF NEW YORK.
SECRETARY, DR. CARL H. DAVIS, OF MILWAUKEE.

The Toxemias of Pregnancy.—Dr. John Osborn Polak, of Brooklyn, N. Y., presented a summary of the present status of the toxemias of pregnancy. The conditions considered in the discussion were: hyperemesis, preeclamptic toxemias, and eclampsia.

Hyperemesis, Dr. Polak said, was the result of a vicious cycle beginning with a carbohydrate deficiency and resulting in starvation and dehydration which produced the final pathology in liver and kidneys. The three underlying factors were: Metabolism, with its carbohydrate deficiency; neurotic hypersensitiveness; and intestinal intoxication with its traditional constipation. The amount of fluid lost by vomiting varied from five hundred to fifteen hundred c. c. per diem. Continuous vomiting produced dehydration. Starvation and rapid emaciation emptied the vessels, lowered blood pressure, gradually increased rapidity of the pulse, diminished the urinary output, increased concentration of body fluids, and lowered the leucocyte count.

The principles of treatment included 1, isolation; 2, exhibition of large quantities of fluid to produce diuresis given by os, by hypodermoclysis, and by intravenous infusion; 3, small blood transfusions with an equal amount of saline solution; 4, in the event of the methods mentioned above failing, pregnancy should be interrupted.

Preeclamptic toxemias were not due to any specialized toxin or toxins, but rather to the overload suddenly placed upon the maternal organism. There were two types, namely, nephritic with a preceding history of kidney lesion, and hepatic (fulminating explosive) with no preceding history of renal disease. Studies in blood chemistry and the basal metabolism rate had little or no clinical significance—*until after delivery.*

In the hepatic type, without a history of a previous lesion, the condition was commonly of sudden development. There was a sudden rise in blood pressure, albuminuria appeared after the pressure went up, and there might be rapid gain in weight followed by edema, headache, and epigastric pain, but the eyes usually showed nothing.

In the nephritic type, the woman began her pregnancy with a blood pressure of 140 or more, a trace of albumin in the urine, and occasional hyaline casts. The phthalein test showed glomerular changes, while the concentration test showed deficient reserve. Headache, edema, eye symptoms, retinal and fundal changes, were present.

The earliest clinical evidences of toxemia were: Rise in the systolic blood pressure, appearance of albumin in urine, diminished urinary output, an increase in body weight, indicanuria, edema of face, hands and feet, epigastric distress (heartburn), frontal headache, and retinal changes.

The treatment of the preeclamptic state and of eclampsia is essentially medical. The treatment of latter month toxemias might be summed up as follows: 1, Prevention; 2, control of the convulsions and coma, and 3, the management of labor in the presence of convulsions when labor has started.

Preventive treatment: The preeclamptic patient should be in bed at rest, her nitrogenous intake limited, and her emunctories stimulated to produce diuresis, diaphoresis and bowel evacuation. In the case of edema the fluid intake must be limited. When the foregoing procedures do not result in lowered blood pressure and increased urinary output, with diminished albumin and improvement in general well being, the pregnancy should be interrupted.

The toxic patient was a poor surgical risk because she bore the anesthetic badly, was liable to shock, had a poor resistance to infection, and could not withstand trauma.

In the presence of convulsions the treatment was never surgical. The indications were: control convulsion with morphine and chloral; protect woman from injury and aspiration of mucus; remove the toxins by bleeding; support the heart; increase elimination and meet glycogen deficiency with intravenous glucose; relieve cerebral congestion with magnesium sulphate. Only after the toxemia and convulsions were controlled should the consideration of delivery be taken up.

The induction of labor was indicated when the patient had recovered from the toxemia—for recurrence had frequently been noted in the same pregnancy. The method of delivery to be employed must be determined by the obstertical factors present in each case.

SECTION ON OPHTHALMOLOGY

CHAIRMAN, DR. ARNOLD KNAPP, OF NEW YORK.
SECRETARY, DR. WILLIAM C. FENNOFF, OF DENVER.

Safeguards in Cataract Expression.—Dr. John Green, of St. Louis, Mo., proposed the following routine in an endeavor to safeguard every step in cataract expression (after capsulotomy):

1. Complete subconjunctival iridectomy four to six weeks prior to the expression.

2. The formation (prior to section) of a trapezoidal conjunctival flap to cover the entire region of the section.

3. The introduction (prior to section) of a Verhoeff suture through the episclera and midpoint of the upper edge of the flap.

4. Downward traction on the four threads of this suture during the formation of the section—to prevent accidental severance of the sutures or base of the flap.

5. Irrigation, if necessary, after replacement and loose suturing of the flap.

6. The insertion of additional conjunctival sutures in each upper angle of the flap.

Loop extraction necessitated by vitreous loss prior to delivery of the lens could be carried out, he said, with ease and safety. Replacement of the angles of the coloboma, wound toilet, etc., could be carried out leisurely and with precision even after vitreous loss. This combination of methods seemed to offer safeguards against infection, serious loss of vitreous, severe iritis and iris prolapse. Visual results in seventy-five cases were given.

Sympathetic Uveitis Caused by the Virus of Herpes Simplex.—Dr. S. R. Gifford, of Omaha, Neb., said that experimental work was undertaken to check up on a report of von Szily who was able to reproduce the clinical picture of sympathetic ophthalmia in rabbits, using material which was obtained from herpetic lesions of the human cornea. This virus was chosen because of its well known property of extension in nervous tissue. Material was obtained from herpetic lesions of the human cornea, which after preliminary inoculation on a rabbit's cornea to obtain a pure culture, was placed in a pouch made between the ciliary body and the sclera of another rabbit. A severe uveitis occurred in the first eye and after about two weeks, when this reaction was beginning to subside, about ten per cent. of the animals developed an iridocyclitis of the second eye. Von Szily's technic was carried out in a large number of rabbits. Besides this inoculations were made directly into the chiasm. Besides pathological examinations of the second eye as made by von Szily, inoculations were carried out with materials from the second eye and from points along the nerves and chiasm to determine the presence or absence of herpetic virus in these locations.

In conclusion, the author stated that 1, the present work confirmed the finding of von Szily that the virus of herpes simplex, when inoculated in a ciliary pouch, will produce in a certain percentage of rabbits a uveitis of the second eye resembling, clinically and histologically, the picture of human sympathetic ophthalmia; 2, it was also possible to produce uveitis of both eyes by injection of the virus in the region of the chiasm; 3, the active virus could be demonstrated in the second eye by positive corneal inoculations and in one case uveitis of both eyes was produced by inoculation from the second eye to a ciliary pouch. A further positive corneal inoculation from the second eye of this animal was obtained, showing transmission of the virus through three generations from the first sympathizing eye; 4, herpes cornea of the opposite eye occurred in six per cent. of the animals inoculated in the ciliary pouch; 5, sections indicated extension of the process by way of the nerves and chiasm to the other eye, and this was confirmed by positive inoculations from points along this route; 6, inoculations from a human case of sympathetic ophthalmia were negative; and 7, the possibility of a filtrable with neurotropic properties similar to those of the herpes virus as the cause of sympathetic ophthalmia was given some support by this work.

The Ophthalmic Year Book, Why and How.—Dr. William H. Crisp, of Denver, Col., said that the *Ophthalmic Year Book,* founded by Dr. Jackson in 1903, more or less along the lines of Nagel's *Jahresbericht* in Germany, was planned to enable ophthalmologists to keep in touch with the periodical literature of their specialty all over the world. Its preparation presents special literary and linguistic difficulties. A thoroughly organized and up to date abstract department to cover the ophthalmic periodicals of the various civilized countries would be in some respects more attractive to the average practitioner, but would be much less valuable for purposes of reference than is the *Ophthalmic Year Book.* The year book has always cost more than was charged for it. To be secure of permanency, it should either pay its way or be supported out of an endowment fund provided privately or by cooperation between scientific organizations.

Closure of the Retinal Vessels: Important Aspects in Diagnosis and Management That May Be Overlooked.—Dr. L. Herbert Lanier, of Texarkana, Texas, said that the cause of closure of the central retinal vessels is not ascertainable from the ophthalmoscopic pictures, but an investigation of the systemic condition may lead to it. One should remember that competent pathologists have made a microscopic examination in very few cases of either central artery or central vein closure, and that sometimes the underlying cause is undiscoverable, as cases have been cited in which closure of the central artery occurred in children not over thirteen, in whom the most careful and exhaustive examination revealed no cause of the closure. We know that, as a rule, a thorough examination will reveal evidence of vascular disease in closure of the retinal vessels, but there are certain exceptional cases arising from time to time to challenge the master research workers in ophthalmology to determine correctly, their etiology. Now, the point that I wish to stress, is that narrowing of the retinal arteries is seemingly possible through contraction of the walls, induced by sufficient irritation to close its lumen, and that such irritation may be due to drugs or other artificial means. It may occur independently of local arteritis or any evidence of arteriosclerosis or any other type of vascular degeneration.

Abstracts from Current Literature

ARTHRITIS

Arthritis Deformans.—L. S. Ashcroft, L. Cunningham, T. P. McMurray and H. S. Pemberton (*British Medical Journal,* July 4, 1925) made a routine study of over fifty cases of arthritis deformans. By opening the joints in a large proportion of the cases they were enabled to recover an organism, which was found to be identical culturally and biochemically in every case. The organism found is different from every other organism described heretofore. It was recovered from the synovial fluid in only one case; in all others it was found either in the membrane or in the articular bone. Experimentally, only rabbits were injected with this organism intravenously, but no resulting lesions were found in the animals. Septic foci, the urine, feces, blood, or fasting gastric contents were all found negative.

The gastic secretion, the basal metabolism, the acid base ratio, the renal and hepatic efficiency, and glucose tolerance tests were all part of routine examinations, and the only outstanding features were the following: achlorhydria or hypochlorhydria in a large proportion of the cases, a practically universal diminution of carbohydrate tolerance, the relative absence of acidosis, renal or liver defects, or changes in the metabolic rate.

The only routine treatment employed was a large amount of 0.4 per cent. hydrochloric acid and a carbohydrate free diet, extending over a period of months. Improvement, as shown first by a diminution of the pain and then by an increase of mobility, was observed in practically every case, even without the elimination of focal sepsis.

Rheumatoid Arthritis.—Humphrey Rolleston (*Canadian Medical Association Journal,* September, 1925) emphasizes the importance of dealing with focal infections prior to the inauguration of any other form of treatment. Then autogenous vaccines, not stock, should be employed. Sensitized vaccines have their advocates, and mixed vaccines may be necessary. Vaccine therapy is often combined with, and said to be helped by, diathermy and ultraviolet radiation. He discusses the long list of drugs used for intestinal autointoxication, the things that have been given to restore an endocrine balance, the prevention of deformities, the way in which heliotherapy, ultraviolet radiation, massage, heat, and hydrotherapy produce good effects, and the protein shock therapy. Finally he propounds the following questions: Is rheumatoid arthritis always infective in origin? What is the relation of tuberculosis elsewhere to chronic arthritis? What share do constitution and disorders of metabolism take in its causation? Are the arthritic and endocrine disorders both due to infection, or does metabolic disorder sometimes precede and dispose to infective arthritis? Treatment by endocrine therapy, dietitic modifications, and protein shock?

Some Features of the Rheumatic Infection.—The records of 141 cases of rheumatic infection are analyzed by Mary Bertram (*British Medical Journal,* March 14, 1925). The patients were examined one to eleven years after the first attack. No case occurred during infancy; sixty per cent. were from six to ten years of age at the onset of rheumatism. Girls were affected more frequently than boys. The disproportion was most marked in the case of chorea (three to one). Arthritis was most prevalent in October and November (thirty-two per cent.), chorea in February and November (thirty-two per cent.). As regards the lesions, seventy-six per cent. of the patients had carditis, seventy-three per cent. arthritis, forty-seven per cent. chorea, twenty-eight per cent. tonsillitis, seven per cent subcutaneous nodules, six per cent. skin lesions. With regard to cardiac involvement, six per cent. had marked cardiac disability, forty-one per cent. slight disability, nine per cent. carditis without disability, twenty-four per cent. had no cardiac involvement. Of the total cases twenty per cent. of the patients died; twenty-five per cent. of the fatalities were within three months, fifty-seven per cent within one year, seventy-five per cent within two years from the onset of the rheumatism.

Pericarditis and subcutaneous nodules were the lesions indicating most severe infection. Early hospital treatment diminished the incidence and severity of carditis. Treatment was more effective in preventing carditis in arthritis than in chorea. Cases of chorea treated by sodium salicylate had a lower incidence of subsequent carditis than cases treated by arsenic, sedatives, or rest without drugs.

Arthritis Deformans.—Alonzo deG. Smith and Samuel J. Ferber (*Archives of Pediatrics,* January, 1926) present an interesting, rapid survey of arthritis deformans. Included is a case from the Vanderbilt Clinic of a girl, eleven years old, together with a differential diagnosis, recommended treatment and bibliography.

Polyarthritis. Report of a Case in an Infant Six Days Old.—In a case of polyarthritis in an infant six days old (*American Journal of Diseases of Children,* February, 1926) L. F. Richdorf and W. H. Griffith conclude that the presence of a similar streptococcus viridans in the mother's blood and the baby's joint fluid, and the absence of local signs indicating a portal of entry after contact or other infection, point toward an intrauterine infection of the infant through the placenta by the organisms circulating in the mother's blood.

Acute Pyogenic Arthritis of the Hip Joint in Infancy and in Childhood.—Morris B. Cooperman (*American Journal of Diseases of Children,* February, 1926) finds that acute gonococcus infections of the hip joint in the newborn are characterized clinically by early, spontaneous dislocations. Immobilization in plaster casts and diathermy are of definite curative value in preventing destruction and relieving the inflammatory reactions. Reduction of the dislocation should not be attempted during the acute stage. Vaccines have proved valueless. Streptococcus and staphylococcus infections of the hip joint in older children are characterized by severe constitutional and local reactions. Intravenous thearapy has proved of little value.

Report Upon Ninety-Two Cases of Rheumatic Disease in Childhood.—Martin O. Raven (*Lancet,* October 3, 1925) divides his report on ninety-two cases of rheumatism, carditis, and chorea into two parts: a, Observations in the wards; b, examination of discharged cases. Experience points to the following three criteria as furnishing the most useful indications of progress or the reverse: 1, Quiescence or recrudescence of symptoms; 2, constitutional signs; and 3, cardiac physical signs.

The recrudescence of symptoms may be summarized as follows: a. Acute rheumatism occurred only once. b. Chorea, once established, has recurred in three cases only—in all of them as a result of a definite emotional upset. In two other cases the movements never disappeared entirely; they appear to be more difficult to check in girls of ample physical proportions. c. Tonsillitis is more common and is troublesome, and the cases are quickly isolated, owing to their being very infectious. d. Simple pyrexia occurs occasionally and, as it yields to salicylates, in most cases, is probably rheumatic; twice it was accompanied by fresh carditis. e. Scarlet fever occurred in one case and was followed by fairly severe scarlatinal rheumatism without further carditis.

Constitutional signs are noted as follows: a. Pallor seldom persists; if it does so it is a bad sign, but a "good color" is often a sign that flatters. b. Weight goes up in all but rapidly deteriorating cases; only a very rapid gain in weight can be taken as a really good sign by itself. c. The nearer the temperature tracing approaches a straight line, the better a case appears to be doing. d. Heart failure occurs only in the severest cases; a heart may be able to respond to a considerable degree of effort while being slowly and progressively infected. Response to effort is therefore no criterion. e. Tachycardia is especially due to the rheumatic poison, quite apart from gross cardiac lesions; in such cases there is little or no respiratory variation in the pulse rate. Correct charting of the pulse rate is very important, since the visit of the doctor may cause a temporary tachycardia. There is no effect of treatment so definite as the change after a longer or shorter period of time, from this rapid excitable pulse rate to one of a more deliberate and uneven rhythm, the first sign of improvement being a noticeable slowing of the rate on slow expiration after a deep breath; as recovery proceeds the sign be-

come more and more marked. Digitalis can sometimes slow the heart rate, but this effect is soon lost.

Among the physical signs of the heart is dilatation of the heart borders, which should be regarded, when following an attack of rheumatism, as evidence of an infected myocardium. It is often accompanied by a systolic murmur which sufficient rest in bed abolishes. The mitral diastolic bruits, described by Cheadle, are very common and are of utmost importance in prognosis, especially as regards mitral stenosis and ultimately auricular fibrillation. The difficult question of valvular infection seems to be more safely dealt with by rest in bed until constant auscultatory signs and a quiet pulse rate show the endocarditis to have been arrested. Aortic murmurs do not appear to undergo any favorable modification.

In the examination of discharged cases the following variable factors were encountered: 1. Number of attacks of rheumatism before beginning treatment. 2. Presence or absence and severity of carditis. 3. Mode of onset of disease—acute, insidious, or choreic. 4. Home conditions of the patient, especially after returning from treatment. (Dampness should be avoided.) 5. Length of time under treatment. 6. Performance or otherwise of tonsillectomy as part of the treatment.

There are so many variations in the conditions to which these patients are exposed, that in order to investigate fairly the results of any type of treatment for rheumatism in childhood, it would be desirable to select a series of cases as uniform as possible.

From reëxamination of these discharge cases one cannot fail to learn that the most accurate prognostic signs are to be found in repeated examinations of the heart; quiescence of symptoms is deceptive, and we have learned that even three years must elapse before it can be assumed that a favorable case is likely to be free from recrudescence. Constitutional signs are also unreliable. If unfavorably developing physical signs can be arrested, as the period of life approaches at which the heart is less susceptible to infection, the chances of an active and useful life are increased.

GENITOURINARY DISORDERS

Stricture of the Ureter.—W. S. Pugh (*Annals of Surgery,* April, 1925) asserts that stricture of the ureter is a definite pathological entity, occurring mostly between twenty and forty years of age. It constitutes about ten per cent. of the upper urinary lesions. It is not purely a focal infection, but due to extension of disease by continuity as well. It is more commonly a gonorrheal process than is generally supposed and its pathology is somewhat similar to urethral lesions. The symptoms are largely local, the diagnosis may be made certain chiefly by history and x ray, aided by ureteral bougie. The treatment is limited to dilatation.

X Ray Kinks of Ureters That Are Not Kinks.—L. G. Cole (*American Journal of Surgery,* May, 1925) warns against interpreting certain x ray findings as definite evidence of kinks, angulations or strictures associated with angulations, in the ureter. The ureter is a flexible tube fixed at the lower end and movable at the upper in proportion to the mobility of the kidney. In both normal and abnormal mobility as seen in the anteroposterior directions, the ureter is relatively straight with gentle curves only; but when observed in the opposite plane these curves are exaggerated, particularly as the ureter comes out of the pelvis and as it crosses the psoas muscle and dips backward to the kidney. In patients with certain physique and with the kidney high these curves are gentle, but in others these curves are quite marked. Thus what are often reported as ureter kinks are in fact but projections of gradual curves.

Papilloma of Ureter and Kidney.—R. V. Day, F. D. Fairchild and H. W. Martin (*Surgery, Gynecology and Obstetrics,* April, 1925) assert that, 1. when a patient has hematuria, or any other symptom likely to be of renal origin, his physician should not be content until he discovers: first, the primary source of the bleeding and, second, the pathological nature and extent of the lesion behind it, if it is reasonably possible by an adequate urological examination.

2. Thorough urological examination may not result in an absolutely accurate pathological diagnosis, but in a general way it does tell the surgeon what to do and notifies him to look for the unusual and unexpected, as well as the everyday pathological findings.

3. Primary nephroureterectomy offers the patient the maximum chance of complete cure, and a two stage nephrectomy and ureterectomy should not be necessary in an increasingly larger percentage of cases if a few simple rules are observed.

4. In the removal of a neoplastic kidney or if there is suspicion of any kind of tumor, splitting and examination of the kidney should be made before closure.

Back Pain of Urological Origin.—L. Michel (*American Journal of Surgery,* August, 1925) states that changes in the position of the kidney, its susceptibility to infection, the common incidence of calculus and silent stone, and the possibility of symptoms being absent, all impress the importance of urologic investigation for obscure back pains. The prostate should also be investigated for infection and carcinoma. Metastases in the spine often occur early in prostatic neoplasm. The accuracy of the cystoscope and roentgenography should be utilized.

Partial Resection of the Kidney.—E. S. Judd (*Annals of Surgery,* September, 1925) finds that it is entirely feasible to perform resection even in cases of solitary kidney, and it should be done whenever a more complete removal of the infection can be accomplished. Resection of double kidney is practical, provided the disease is definitely confined to one segment. Just as in cases of solitary kidney the resection can undoubtedly be made whether the kidney is double or single. For the present, one should be contented with nephrectomy in most cases of tuberculosis. Even in what appears to be very early cases, the infection usually involves more of the renal tissue than can be demonstrated except by microscopic examination. Before resecting renal tissue, we must take into consideration the amount of renal hypertrophy and atrophy, so that we may save a segment of the kidney that will be of some service to the patient.

Etiology and Treatment of Cystitis.—H. W. B. Cairns (*British Journal of Surgery,* July, 1925) divides cases of cystitis into two main groups: Those which clear up quickly either spontaneously or after simple forms of treatment (resolving cystitis); and those which become chronic (progressive cystitis).

The paths of bacterial infection in resolving cystitis are not completely understood. In some cases the infection undoubtedly comes from the kidney, in others possibly from the prostate. There remain, however, many cases in which it is impossible to determine the source of the infection.

Chronicity in cystitis is due to a number of conditions. In rare cases it is due to a solitary ulcer of the bladder, a condition of unknown etiology. In most cases it is due either to persistent infection from the kidney or to the presence of retained (or residual) urine in the bladder.

A persistent focus of infection in the renal pelvis may give no clinical sign. Evidence obtained by cystoscopy is frequently of great value in the detection of such foci. If the lesion of the renal pelvis is treated efficiently, the cystitis will clear up at once.

Any variety of retention of urine may produce progressive cystitis. The successful treatment of retention cystitis depends entirely on the establishment of complete drainage of the bladder either by natural or artificial means. Bladder irrigations are of great service in this variety of cystitis.

When cystitis occurs in a case of unrelieved acute retention there is grave danger that it will be followed by ascending pyelonephritis, a condition which is usually fatal. When it is realized that all cases of retention of urine require immediate and complete relief, then only will ascending pyelonephritis, the occurrence of which is a grave reflection on the teachings and practice of surgeons of today, cease to be common. Drainage of the distended bladder is an operation of greater emergency than that of drainage of a pelvic abscess.

Finally, cystitis, though a distinct clinical entity, is usually secondary to some other lesion of the urinary tract. It should not be treated empirically; the exciting and predisposing causes should be sought by a thorough investigation of the whole of the urinary tract. When these causes have been dealt with, the inflammation of the bladder will subside of its own accord.

Persistent Pyuria.—J. A. Lazarus (*American Journal of Surgery,* August, 1925) discusses this complication as a sequela of prostatectomy, and concludes from his cases that:

1. The prostate gland is usually not removed in its entirety at prostatectomy.

2. The residual prostatic tissue and seminal vesicles frequently become infected during a prostatectomy and perpetuate a pyuria. This should make it imperative, in searching for a focus responsible for a persistent pyuria, to massage the prostatic region and vesicles for pus.

3. The residual prostatic tissue is often the seat of recurrent tumor formation with infection.

4. Pyuria can be due to the presence of a bladder tumor easily overlooked at the time of prostatectomy.

5. Infected diverticula constitute a common cause of pyuria in cases of hypertrophy of the prostate. Cystograms should be made in all cases of persistent pyuria following prostatectomy.

6. The commonest cause of pyuria in prostatectomized patients is the presence of infection in the upper urinary tract. This should be investigated with careful postoperative cystoscopic examination of the kidneys.

Condylomas of the Penis Simulating Cancer.—A. Buschke and Ludwig Loewenstein (*Klinische Wochenscrift,* September 3, 1925), as a result of their histological investigations, come to the conclusion that these cases show an excessive growth of condylomata acuminata, which present no atypical cells and no definite destructive cancerous growth. Their partially infiltrating growth is the only symptom, which, from a pathological viewpoint, would entitle them to be considered as carcinomas. Inasmuch as all the other histological and clinical signs bespeak a condylomatous nature, they should not be taken for carcinomas. The fact that infiltrating growth with pointed condylomata has not been observed in females, suggests the possibility that certain anatomical conditions in the male genitals are responsible for their development. In the first place, it should be mentioned that in every case observed there was a congenital phimosis, which at least exerts a permanent irritation upon the underlying tissues and, as a result of the continuous retention of smegma, incites the existing vegetations to this extraordinary growth. Furthermore, the contracted prepuce, which limits to a certain extent the extension of the papillomatous growths upward and laterally, exerts a mechanical cause by pressure from without and favors of the growth of the epithelium into the depths. At any rate, the continuous inflammatory irritation, which expresses itself histologically in the enormous infiltrations, is certainly sufficient to cause proliferation of the epithelium, and if this is continued for years it results in forms of growth that closely resemble carcinoma, without partaking of their character.

Inasmuch as conservative treatment failed because of the profound anatomical changes, the authors felt justified in amputating the penis in a number of cases. More recently, if the benign character of the growth was proved, the use of röntgen irradiation and radium was tried, especially since the latter is very useful in cases of condylomata acuminata.

Urethral Stricture.—A. Hyman (*American Journal of Surgery,* June, 1925) maintains that practically all urethral strictures can be dilated successfully by means of filiforms with Philips bougies or catheters. When these instruments cannot be passed it is advisable to resort to suprapubic methods to relieve the distended bladder, rather than operating upon a badly traumatized urethra. The measures briefly outlined below have worked out so admirably in the order mentioned, that they should be the methods of choice in the treatment of uncomplicated urethral stricture.

I. Dilatation with Philips filiforms and catheters. Many of the patients applying for relief have already been traumatized by ineffectual attempts to pass instruments. Further instrumentation should therefore be avoided for six to twelve hours, in the meanwhile administering hot sitz baths and opiates. If there is complete retention and relief is urgent, attempts to pass filiforms should be carried out as follows:

1. Anesthetize urethra with two per cent. novocaine.

2. Distend urethra with sterile albolene. This helps to iron out all urethral folds on which filiforms are likely to impinge.

3. Introduce four to six Philips filiforms and manipulate until one passes the stricture, this may require considerable time and patience but by this method most strictures can be passed.

4. When a filiform is in place, half the battle is won. A bougie or, preferably, Philips catheter is screwed on and passed into the bladder. Every twenty-four to forty-eight hours a larger size catheter can be inserted, using the filiform as a guide without removing it from the urethra. If the stricture is so tight as to permit the passage of only a filiform it should be strapped in place for one to two days, after which it will be found easier to introduce a catheter or bougie screwed on to the filiform.

The average stricture by this method can be dilated up to twenty to twenty-four F. within a week, after which ambulant treatment is carried on.

Should the above outlined method prove unsuccessful, the following procedures are to be carried out:

1. Suprapubic puncture with Potain suction apparatus. The distended bladder is aspirated suprapubically by means of a Potain suction apparatus. Some cases have been aspirated three to five times. This allows the edema to subside, so that filiforms may be tried again at the end of two to three days. The procedure gives the traumatized urethra a rest, and danger of contaminating the peritoneal cavity during puncture is very slight.

2. Suprapubic buttonhole drainage, with or without retrograde catheterization. Under local anesthesia, the bladder is exposed suprapubically by a small incision and a large trocar and cannula are inserted. The trocar is removed and a catheter is introduced through the cannula into the bladder. This is a simple procedure and takes but a few moments, and cannot be compared with the difficulties encountered in attempting an external urethrotomy without a guide. The catheter is left in place four to seven days, making no attempts to instrument the urethra in the meanwhile. As a rule, at the end of a week, a number ten to fifteen F. bougie may be passed at the first attempt without any difficulty.

3. Retrograde dilatation.—Should it not be possible to introduce a bougie or filiform, after the urethra has been given a rest from instrumentation, a cystoscope is inserted through the suprapubic opening, the internal sphincter orifice is located and catheterized with a ureter catheter which is allowed to remain in place three to four days. Retrograde passage of bougies or catheters will occasionally succeed when other methods fail. Often when bougies cannot be passed in the normal way, ureter catheters may be introduced retrograde without difficulty.

Control of Venereal Disease.—H. W. Bayly (*International Journal of Medicine and Surgery,* September, 1925) reports as follows upon the evidence of witnesses called before the Trevethin Committee of Inquiry regarding the value of immediate self disinfection as a method of preventing venereal disease.

Three questions were submitted, viz: 1. Have you any evidence of the effect of the application of such disinfectants immediately after exposure and after the lapse of two, four, six, eight, ten hours or longer? 2. Does the application of such disinfectants either immediately after exposure or at a later time require particular skill? Can it be carried out by a man, or a woman, of average intelligence in a state of sobriety? 3. Have you any evidence to show that a large proportion of persons who contract venereal disease are infected while under the influence of alcohol?

On summing up the evidence submitted in reply to these three questions it was found that everyone who had had personal experience in the prevention of venereal disease by immediate selfdisinfection was wholeheartedly in its favor as a valuable means of preventing these diseases. In answer to the question as to whether selfdisinfection requires particular skill in men and women there was almost unanimous opinion that immediate selfdisinfection was much more difficult to carry out in women than in men, and that it could not be carried out by women unless a comparatively complicated apparatus and considerable quantity of disinfecting fluid were available. Miss Rout's evidence showed that in certain particular instances immediate selfdisinfection in women is of value. As regards men, thirteen considered that no particular skill was required and six that skill was required. These six had little if any personal experience, and their opinions were based on theory rather than practice. In reply to the question in regard to the relationship of alcohol and venereal disease opinion appeared to be almost equally divided, the balance being slightly in favor of the conclusion that alcohol is not an important factor. Figures produced by two witnesses, showed that alcohol appeared to be an unimportant factor.

Medicolegal Notes.

EMPLOYEE OF HOSPITAL NOT LIABLE FOR NEGLIGENCE OF FELLOW EMPLOYEE

Plaintiff, on the advice of her family physician, went to a charitable hospital to have her tonsils removed by the x ray method. She was there introduced to the hospital's x ray technician, who was not a licensed physician. While administering the third treatment he neglected to use a filter, and as a result plaintiff suffered an injury for which she sued the specialist in charge of the hospital's x ray department, who received for his services one half of the fees paid to the hospital for x ray work. The defendant was not consulted by the plaintiff, nor did the latter see him at any of her visits to the hospital. He testified that he prescribed x ray treatments, but did not administer them or take x ray pictures; that this work was done by the hospital's technician, to whom he gave directions for the x ray treatment of tonsils.

The technician was not employed by the defendant. He was not the defendant's agent or servant. They were fellow employees of the hospital. The Massachusetts Supreme Judicial Court holds, Withington v. Jennings, 149 N. E. 201, that the defendant was not responsible for the technician's neglect in administering the treatment which was entirely in the latter's control. The evidence did not show any negligent act of the defendant contributing to plaintiff's damage; he did not participate in the operation, and was not liable for her injury. It was held that a verdict was properly directed for the defendant.

BINDING EFFECT OF MEDICAL EXPERT EVIDENCE

In a proceeding to review an award of compensation for the death of a workman who fell from a scaffold, fracturing his skull, the question was whether the fall was caused by a stroke of apoplexy, which was shown by a pontine hemorrhage in the deceased's brain, or whether the fall preceded the stroke. The autopsy showed an extensive subdural hemorrhage covering the base and lateral surfaces of the brain, and a basal fracture running across the basal fossa of the skull. There appeared to be no doubt that this subdural hemorrhage was due to the basal fracture of the skull, and that this fracture was occasioned by the fall, and both together were sufficient to cause death. There was nothing in the physical appearance or condition of either the pontine hemorrhage, or the fracture of the skull and the subdural hemorrhage caused thereby, to indicate which of the two occurred first in point of time. The medical experts gave as their reason for their statement that the apoplectic stroke preceded the fall the fact that the pontine hemorrhage was not traumatic. The Industrial Accident Commission disregarded the opinion of the medical experts, and found that the fracture of the skull caused by the fall and subdural hemorrhage therefrom were the proximate cause of death and made an award therefor.

The California District Court of Appeal, Second District, William Simpson Const. Co. v. Industrial Acc. Commission, 240 Pac., 58 (hearing denied by Supreme Court, Oct. 22, 1925), says that the rule to be drawn from the decisions of the California courts as to the binding force of medical expert testimony appears to be that whenever the subject under consideration is one within the knowledge of experts only and is not within the common knowledge of laymen, the expert evidence is conclusive upon the question in issue. It follows that in such cases neither the court nor the jury can disregard such evidence of experts, but, on the other hand, they are bound by such evidence, even if it is contradicted by nonexpert witnesses. The same rule would, of course, apply to a proceeding before the Industrial Accident Commission. Under this rule, the Commission, in the present proceeding, could not reject the evidence of the medical experts when testifying upon any subject peculiarly within their own knowledge. The same rule would apply as to opinions of the medical experts upon a subject solely within their professional knowledge, and not within the knowledge of the ordinary individual.

EVIDENCE OF LICENSE AS OSTEOPATH HELD ADMISSIBLE IN PROSECUTION FOR PRACTISING WITHOUT LICENSE

In a prosecution for practising medicine without a license, the Iowa Supreme Court holds, State v. Cornelius, 204 N. W. 222, that it was error to exclude evidence that defendant was a regularly licensed osteopathic physician, since, if what he did in the way of diagnosis, treating patients, and prescribing and giving medicines, was no more than he was authorized to do as an osteopathic physician, he was guilty of no crime. But a license as an osteopathic physician would be no protection if he gave or prescribed internal curative medicine.

If prescriptions signed by defendant were merely in the nature of orders for medicines to be kept and used as required in the hospital where he was employed under a physician, it is held that they had no tendency to establish the charge and should not have been admitted, but if they were given to patients for the purpose of having the medicine prescribed taken, they were admissible.

The trial court instructed that if defendant did no more than carry to patients medicine prescribed by a regularly licensed physician by whom he was employed he could not be convicted, but that he had no right to prescribe any medicine, even under the supervision of such physician. It is held that if defendant was authorized to practise as an osteopathic physician, he had a right to prescribe such medicine as the law permitted him to prescribe, but that otherwise the instruction was correct. Under Iowa Code of 1924, §2538, it is only students who have had not less than two courses of lectures in a medical college of good standing who are permitted to prescribe under the supervision of a preceptor.

The fact that defendant prescribed or administered medicine under the direction of a duly licensed physician, if he had no right to do so at all, or if he prescribed or administered medicine that he, as an osteopathic physician, was prohibited from prescribing or giving, would, it is held, afford him no protection.

Judgment on a verdict of guilty was reversed and the case remanded for a new trial.

THIRD PARTY'S PROMISE TO PAY FOR MEDICAL SERVICES FOR CHILD

The Georgia Court of Appeals holds, Pope v. Ellis, 129 S. E. 11, that where a physician renders professional services to a minor child of the tenant of a building, solely upon the credit of the landlord's promise to pay for such services, the promise is an original and not a collateral undertaking, and is not within the statute of frauds. In this case the jury were held authorized to find, from the evidence, that the landlord (the defendant) did make, in substance and effect, such a promise. In such a case, it is held, the jury may find that the promisor is liable for the services of the doctor, even though the father of the child treated was ignorant of the contract between the promisor and the doctor, and regarded himself as solely liable for such services.

Conceptions of Modern Philosophy and Their Application to Medical Science*

HEINRICH F. WOLF, M.D.

New York

It is well known that at the time of Hippocrates medical men were likewise philosophers. Gompers in his wonderful book, *Greek Thinkers,* has given a splendid account of the achievements of this school. But the introduction of philosophy into actual medicine was very dangerous at a time when theoretical knowledge in medicine was very limited, and so it came about that wild speculation replaced scientific observations and conclusions. When Johann Mueller banished speculation from medical science he did the greatest service to our profession.

But times have changed. Just as it is possible nowadays to perform operations which would have meant certain death before asepsis was introduced, so it might be possible now, not only without harm but to great advantage, to reintroduce philosophical ideas into medicine.

Before entering into the subject proper of my paper, I should like to show you in two instances how valuable the applications of formal logic could be to our medical discussions. A number of times the subject of disappearing tumors was brought before this society. If no conclusions were reached it was not due to the difficulty of deciding the issue but to the disregard of an important logical fact. You know that induction is the basis of all our knowledge. On that account the syllogism Barbara is incorrect. We say for instance: All humans are mortal. Mr. Smith is a human being, therefore he is mortal. This syllogism is in fact valueless. We only know from experience that all human beings die, but in the strict scientific sense we can not make that statement as long as Mr. Smith is living.

In this case, of course, it sounds ridiculous, but if you apply the same syllogism to cancer you will see how the mistake crept in.

We thought that all tumors which histologically appeared to be cancers were malignant and drew the following conclusions: All cancers are malignant; this tumor is histologically a cancer, therefore it is malignant. We were not entitled to say that all such tumors were malignant, but that they have a malignancy of various degree. Some of them develop very quickly, others disappear spontaneously. If such a tumor had disappeared once only in the memory of man the conclusion would have always been uncertain.

Another mistake, this time against the principle of relativity, was made by my distinguished friend and member of this society, Dr. Oberndorf, in a paper recently published in a German periodical. He reports the case of a man in whom a psychosis developed from the fact that his penis was abnormally large. He argues against Alfred Adler's theory of psychosis, which is largely based on the conception of *Die Minderwertigkeit der Organe.* He says that in this patient the psychosis developed on account of an *Ueberwertigkeit.* This, of course, is not correct, as the patient, and he is the one to be considered, felt it as a handicap, what in this case it really was. Values are, according to the Austrian school of political economy, always subjective and therefore relative. To him the anatomical abnormality was a misfortune, and I am sure that the good result obtained was due to the fact that, once the cause of the psychosis was found, it was possible for the doctor to convince the patient that his trouble was not so serious after all.

John Morley, in his book on compromise, speaks of the utility of error. He comes to the conclusion that though one can not deny that error, untruth, may have its blessings, the harm done by it far outweighs its advantages. John Morley deals in this book mostly with religious and political problems. It would, however, be interesting to look at this problem from the broadest point of view. First of all it may be necessary to show how inadequate our language is to express our thoughts. An error is a deviation from truth. Untruth is contrary to truth and reality. That seems on the face of it perfectly clear, but I shall try to show you, on the basis of the writings of Hans Vaihinger (the most important of which is the *Philosophy of the As-If*), that the definition is not complete, as it does not take into account that an error, an untruth, or a fiction, can be purposely, voluntarily and successfully used in search of truth. An error, untruth, according to the sense of John Morley, is an intentional deception used for the sake of deception. An error, untruth, fiction, used according to Vaihinger, is a conscious, intentional use of an error as an aid in the search of truth. Error,

*Read before a meeting of the Metropolitan Medical Society.

Copyright, 1926, by A. R. Elliott Publishing Company.

untruth, in the first meaning is intentional, kept up to perpetuate the deception; in the second, it is used only as a stepping stone, a device, or, as the Germans say, *ein Kunstgriff*, a form of mental economy, and it is corrected as soon as its purpose is attained.

Thus, before entering into the discussion of its application to medical science, let me pause an instant and give examples from the exact sciences. We speak of the circle as if it were a polygon with an infinite number of sides, and we figure its area by this means, although we know that a circle is not a polygon. We speak of ether in physics as a substance without weight, offering no resistance, noncompressible and absolutely elastic. This is clear nonsense from the layman's point of view, impossible, contradictory. Still, this conception has been most useful in the theory of electricity. We call a circle an ellipse, the foci of which are infinitely close and in this way we can apply the equation of the ellipse to the equation of the circle by making the distance equal to zero. In mathematics we deal constantly with infinitely small figures that are purely fictitious but still the results are correct because at the end of the problem the infinitely small figure is made equal to zero and so are all the products and can be dropped out of the calculation, making the results correct. The root of -1 is called an irrational figure. It has no meaning and is still most useful.

Fictions, as such, have been used in all sciences. Adam Smith in his *System of Economics* made the supposition that every human act is directed by egotism. This is obviously untrue, but if he wanted to develop his theory and show the basis of an economical development, he had to disregard what was not absolutely essential—what did not fit into his system for the time being, at least. The person who wants to develop general ideas has to exclude certain facts nonessential to his system to avoid being drowned in a sea of detail, just as the painter puts on his canvass what he considers essential to illustrate his impression. Adam Smith's assumption is evidently fictitious, and it is clear that there are many other factors controlling the individual as well as nations, though egotism is obviously the strongest.

The object of these examples is to show that we can get correct results in spite of the use of untrue, contradictory, erroneous premises. This is possible only by correcting the error after the result is achieved. It is sufficient to realize the fictitiousness of an assumption and to look at it merely as a device, and not to regard it as an hypothesis or theory which must eventually conform with reality.

If we once realize the fictitiousness of some of our assumptions, we could save ourselves a great many discussions, correct a great many of our errors which develop from conclusions based on false premises. These mistakes are due to our misunderstanding of the essence of language. Language does not represent reality; it is not generally recognized that the logical functions have nothing to do with the objective world; their ways and detours must not be mistaken for real happenings. They are entirely different, but its value manifests itself by the fact that the logical functions, working according to their own laws, coincide again in the end with reality (Vaihinger).

Let us now apply these ideas to medicine. The teleological point of view has been a very much debated topic. That there is a ruling and directing power is hotly denied by some and strongly supported by others, to whom it seems the only possible way of explaining the development of higher forms of life. Could useful mechanisms develop if this development were not guided by a conscious power? I do not wish to discuss this problem, except by pointing to the works of Rudolph Goldscheid who showed that motion is not conceivable without direction; that development is motion and that the development into higher forms can easily be explained by Darwin's *Survival of the Fittest*.

It is undoubtedly proper to apply the idea of teleology to the medical science, and it has a very beneficial influence indeed. Not so long ago we did not understand the importance of the ductless glands, the pineal body, the hypophysis, the thymus and other such organs which were looked upon more with curiosity than with interest. But they exist, and it is of the very greatest value to think that they exist for some purpose. This conviction induced many to look for their use and we know now that these organs are of vital importance for the existence and development of animals as well as human beings. The mistake we made was to regard teleology as a hypothesis or theory rather than a fiction. We know that a group of physicians think of the appendix as an integral and important part of the body because it exists. I need not say that surgeons here and in other places do not share this view. I do not want to say that this idea is necessarily wrong and that studies to that effect may not be proper. But the fact that the appendix exists is no proof whatsoever that it is of any value just because teleology is not a hypothesis but a fiction.

According to Vaihinger, an hypothesis can be proved to be correct and a reality. Fiction is always untrue, contradictory, arbitrary. To show the difference more clearly, I shall give you two instances. Formerly, before the Wassermann test was known, we treated cases as if they were luetic. If our supposition was correct—if the treatment succeeded—we considered the fact as proved, *ex iuvantibus*. If not, the hypothesis was wrong.

Cancer was considered by many physicians as caused by amebæ. Dr. Richard Lewisohn, of New York, treated some patients by emetine, as if this assumption were correct. The result was negative. The hypothesis was proved wrong.

The teleological viewpoint, however, contains elements which are absolutely contradictory. It is a fiction. But, as previously shown, this does not make the use of it impracticable, harmful, unjustified. The trouble begins when we use it as an hypothesis or theory instead of merely a fictitious idea, a stepping stone, for reasons of mental economy.

Another fictitious idea used so much in medicine is the norm. It is hardly necessary to say much on this point. We know that the norm does not exist, that it is pure fiction. Norm does not mean anything else but the average, average in itself is nonexistent. Norm has nothing to do with usefulness. The shortsighted eye is far more useful to the scientist who uses his eyes for reading or microscopy. The artist's eye sees things quite differently from the way we see them, and it is this difference probably that makes

them artists. The normal visceral sense is poor, a very important fact, as an increased sense would make us unfit for work. Still, a finer sense would probably tell us pathological sensations in the body before the cause of that sensation becomes incurable. Think what a blessing it would be if a patient could tell us that he felt pain in the upper ileum or the liver or the pancreas, etc., as he can when the left foot or the right ear hurt him. It is true that many people know that the norm is only an artifact—being identical to the average. Many unnecessary researches have been made to establish as correct an average as possible, but when it comes to application, the results are useless and often misleading. In the tables of a health organization the normal blood pressure is given dogmatically for every age.[1] This is necessarily misleading, as blood pressure is so labile that the change of 5 to 20 mm. is of no importance whatsoever. In fact, the increase in the average blood pressure as found with increasing age is only due to pathological changes in many old people. Nobody ever died from having a blood pressure of 120.

The greatest trouble we experience, however, is in the process which we call "making a diagnosis." What does diagnosis mean? To make a diagnosis means to classify a given case from the pathological point of view. If we analyze this procedure, we must see at once that this means grouping with analogous cases where similar findings have been made. The definition of analogous implies that there are no identical cases. As a matter of fact, there are no identical diseases and there are not even diseases —but diseased human beings. Strictly logically speaking, there is no identity. What we call identity is only continuity based on memory. Boltzman, the famous physicist, used to say that the same person is different if he stands in another corner of the room, as the gravity and the relation of masses is changed. A man is different today from what he was yesterday or will be tomorrow because the metabolism is constantly changing. A person might be immune against an organism today, and might fall victim to it tomorrow probably because his endocrine makeup has changed. If diseases were identical, we should not experience such different development. We should not see patients recover or die from the "same disease." A disease is the result of the condition of the patient and the nature of the conditions.

I realize that this is sufficiently appreciated, but just as a man may be religious or ethical in theory but does not practice his conviction in his daily life, so a large majority of physicians do not apply this fact in practice. They may say that they know it, but in their discussions no trace of it is to be found. Take, for instance, the group of diseases which include Hodgkin's disease, lymphosarcoma, lymphoma, lymphoadenoma, etc. In every discussion on this subject, for instance in this society, physicians try to analyze these forms and to subdivide them—perfectly unnecessarily. It is true that certain forms retain always the same characteristics by which they are classified, but the borderline cases are those that show the classification to be perfectly arbitrary—fictitious—misleading. Often we have to revise a diagnosis, not because the classification was incorrect at the outset but because we did not take into consideration the further development of the disease and the possibility of its changing into another form.

What physicians are trying to establish is a type. But it is not difficult to show that type is fictitious, that there is no type. We create a type by disregarding certain minor symptoms—certain nonessential traits—exactly in the way we formulate an idea. I must repeat that this does not mean that we should not try to establish a type. If we want to understand each other, we have to use types as a method of mental economy. It would be practically impossible to discuss anything if we could not abbreviate certain mental mechanisms by condensing them into words. Teaching would be entirely impossible, and it is just in teaching where the establishment of a type is of greatest help. In a clinic we try to demonstrate a case as nearly akin to the type as possible to develop a picture in the mind of the student, but we fail to explain to him that this type is nonexistent, and when the student enters practice, he must feel like a man among strangers though they may speak a familiar language. In the making of a diagnosis the classification is necessary. Without classification we could not learn, we could not teach, we could not understand each other, except by minute descriptions of details which would only be perplexing. But this realization should make us tolerant. Not so long ago we were taught that there are two forms of pneumonia—lobar and lobular. Now we have divided it into many groups, have found that they are mostly mixed infections, and it may not be long before we shall analyze each case not only according to the kind and virulence of the invading organism, but to the special importance of each of the species in the clinical picture. It is probable that the patient who carries in his lungs more of the organisms belonging to one group and less of the other may have more chance to survive than the others. Here we see the type has practically disappeared and an entity has been established which excludes the possibility of an identical case.

This shows that even in infectious diseases a rigid statement cannot be made. Far more difficult is it in cases where an infinite variety of conditions may exist—for instance, in the realm of endocrines.

It is generally said that the character and the very essence of the individual is founded on his endocrine makeup. If we realize the possibilities, we shall understand that from the viewpoint of endocrinology an identity or even type cannot exist. Until now endocrinologists have confined themselves to determining the symptoms which endocrine disturbance has produced. They tried to show how the functions of the endocrine glands differ from the average and how they influence the functions of other glands. By closely analyzing these facts they have been able to arrive at the therapy which went straight to the root of the cause of the symptoms. But already we see a tendency to establish types for the purpose of teaching and communicating. We call a case hypothyroid or hypoadrenal. The result is that they have to admit at once that a case that looks like hyperthyroidism is not a true hyperthyroidism, but that this

[1] Some time ago, a patient thirty-five years old, who had been examined at this health organization, came to me in mental distress, asking me to help him. His blood pressure was too high. It was 130 mm. In the table given, with this examination, the normal blood pressure for his age was limited to 124—not 125, nor 123—124 exactly. Every physician knows that this is nonsense.

increase in the thyroid gland is caused by inefficiency of another gland. This warning which is so often sounded would not be necessary if we would learn to understand that types must only be used as a device.

I do not think that when a physician speaks of a disease he has a type in mind, but a diseased person. When I speak of tabes, I think of certain cases of tabes which I saw. How could I otherwise class the bedridden patient with the man who does not show more than the subjective symptoms, such as pains. How often does it happen that such patients show only such slight symptoms that we call them abortive cases. Classifications are necessary, but we must never forget that they are only artificial, fictitious, useful for mental economy, but, after all, devices. This is most important when it comes to the treatment of diseases. It is still quite a common practice for a physician after making a diagnosis to look up his prescription book, whether actually or not, and prescribe a medicine which Dr. A, B or C has recommended. If we once would realize that we deal with sick people and not with diseases, we could never do this. It is true we speak of indications to treatment but this is done not methodically but practically. Let me illustrate this fact by my experience in physical therapy.

A patient is suffering from an infectious arthritis. We know that these conditions are due to an invasion of organisms which may have a special affinity for articular tissues, and we shall try to find and eliminate this cause. Whether we are successful or not, we proceed with the treatment. Most physicians prescribe salicylates and then physical therapy, while others condemn the use of the latter. Both are equally wrong. The success depends on the condition of each individual joint and its treatment, so it may happen that we have to treat the acutely inflamed joint with ice and another joint of the same patient with wet dressings and massage because the process has become subacute, and still another joint might need heat, as the process has subsided and we have to deal with the local results of the infection only. The treatment, therefore, does not depend on the diagnosis but on the local condition.

Someone may say that I advocate symptomatic treatment. My answer is that the indication termed *indicatio causalis, morbi and symptomatica* is entirely misleading. For example, take the blood transfusion. Such a transfusion in a patient with a tenia solium is strictly symptomatic as long as the tapeworm is not driven out. It is symptomatic in pernicious anemia, as the patient dies eventually. It is symptomatic in the case of hemorrhage in typhoid fever. But repeated transfusions may pull the patient through the stage where such hemorrhages occur and may save him. It is not symptomatic where a patient has lost blood by injury, but it is symptomatic when it is lost in the course of a pathological process and still lifesaving if it permits us to relieve this pathological condition by an operation. The relief of pain by a morphine injection in a case of tabes is a symptomatic treatment of passing value. But such an injection can save the life of a man who suffers from an attack of angina pectoris, though it does not cure him. If one treats an acutely inflamed joint in the proper way, one may be able to restore complete function of the affected joint even if it is not possible to find and remove the underlying focus. The fault which we find with the symptomatic treatment is only based on a logical error and is due to a wrong interpretation of the word. Treatment of hypothyroidism with the thyroid gland is, so to speak, a symptomatic treatment, but it can replace the missing function of the thyroid gland. Endocrinology is more or less based on socalled symptomatic treatments. But after all, the symptoms form a complex which we call a disease.

All this does not mean that we must abandon entirely routine treatment, and that we must not profit by the experience in other analogous cases, but we must not be dominated by such a routine. Many will say that the good experienced physician individualizes. He does so not logically or consciously, but empirically. Does not Socrates say that he prefers the man who does wrong consciously to the man who does right unconsciously? If a physician is confronted with a given case, his mental process is generally as follows: Case B resembles Case A where the treatment was successful. His mental process, however, should be, Case B has the symptoms a, b, c, d. I wish to treat these symptoms in such a way that the patient may return to his normal condition. I could accomplish it if I could produce the reaction 1, 2, 3, 4. Which of my methods will be useful in accomplishing this task?

To show another instance where the lack of philosophical reasoning has brought about an endless, fruitless discussion, I may mention Freud's works. No exception could be taken, no objection could be made to the Freudian methods and ideas if we would look upon his ideas as fictitious instead of as theories or hypotheses. This would allow us to exclude cases which do not fit into his system instead of forcing them into it.

There was a time when philosophy directed the medical sciences. Speculation stood for observation and hampered the progress. These times are happily past but the fear of speculation estranged the physicians from philosophy even now when philosophy no longer deals with metaphysics, but with the foundation of our thinking, our cognition. It is deplorable, as it strengthens us in our belief that our methods are correct and infallible. The exponents of exact sciences have long recognized this.

In conclusion, I wish to reiterate once more that I do not mean to say that it would be advisable to do away with our present way of thinking, talking and acting, that everything that we considered to be true is an error. This is not the case. Classification, forming of types, rules, establishing of norms as a starting point, are absolutely necessary to progress. Everything in the world exists only in relation to something else, and therefore we must have a starting point or an accepted standard. These things are only conventions—therefore not facts but fictions. Our system of thinking and working is of great value in obtaining an object but we must not forget that its value is not greater than the help it affords us. It must not dominate us. I had a teacher who told us, "Gentlemen, do not let any patient die without a diagnosis." He meant well but he was the worst diagnostician, and was still worse as a physician. Diagnosis must not be a fetish if it means classification.

The Placing of Thoracoplastic Cases in General Surgical Wards and Their Medical Care Thereafter*

S. ADOLPHUS KNOPF, M.D.
New York

The more and more gratifying results obtained in late years from thoracoplasty in far advanced cases of pulmonary tuberculosis have created the desire to give the benefit of such surgical treatment to the consumptive poor as well as to the rich, but in the state of New York a serious obstacle has been met in the law which forbids tuberculous patients being admitted into the surgical wards of the general hospital. This law was enacted some years ago on the recommendation of the state board of charities.

Dr. Willy Meyer called on me recently wishing to ascertain my personal opinion on the alleged danger of spreading the disease when a tuberculous patient on whom thoracoplasty has been performed is placed in the surgical ward of a general hospital. I felt then, as I feel now, that I could answer this question by saying that in the well conducted, sanitary hospital of today there is no danger whatsoever to adults. But in such a vital matter as this I believe one man's opinion should not count for much and I promised Dr. Meyer to collect the opinions of some of our leading tuberculosis specialists and sanitarians on the subject. For this purpose I addressed the following question to each of the names selected as authoritative and representative:

Does any danger arise to patients suffering from other diseases when a tuberculous patient who has been operated on by means of extrapleural thoracoplasty, for rib resection or cutting or avulsion of the phrenic nerve is placed in a corner of a surgical ward of a general hospital?

In reply to this inquiry the following physicians stated their entire agreement with me: Edward R. Baldwin, of the Trudeau Sanatorium; Sherman G. Bonney, of Denver; Kennon Dunham, of Cincinnati; Charles J. Hatfield, of Philadelphia; Maurice Fishberg and James Alexander Miller, of New York; George M. Kober, of Washington; Allen K. Krause, of Baltimore; Walter J. Marcley, of Minneapolis; Charles L. Minor, of Asheville; Edward O. Otis, of Boston; F. M. Pottenger, of Monrovia, Calif.; Joseph H. Pratt, of Boston; E. Richmond Ware, of the Barlow Sanatorium, Los Angeles, and William Charles White, of the United States Public Health Service. The last named gentleman even added the following significant words: "I would strongly urge the elimination of all such expressions as 'placing in a corner surrounded by a screen, or cubicle.' This only postpones the day of beneficial care of those afflicted with tuberculosis."

It might be interesting to note all the additional comments that were made on the situation, but as it is I will quote only a few.

Dr. Baldwin said: "You have hit upon a very real problem in the modern treatment of tuberculosis and I confess it is a puzzling thing to work out. As you know, there is a great deal of hypocrisy in this matter of treating tuberculosis in hospitals, or for that matter also in hotels, both in country and city."

Dr. Dunham said: "You are bringing up a very timely and important subject and I am glad to give it all the support within my power."

Dr. James Alexander Miller said: "In my opinion, a good many of these rules about taking tuberculous patients in general hospitals are antiquated and not in line with modern medical knowledge."

Dr. Allen K. Krause, of Johns Hopkins University, the editor in chief of the *American Review of Tuberculosis,* whom we consider one of our best authorities in his specialty, wrote as follows: "I do not see how a patient with pulmonary tuberculosis, who has undergone a surgical operation, can be dangerous to his neighbors in the wards of any hospital that is being administered according to present standards of hygiene and the ordinary precepts of modern care and sanitation of the sick. For such a person to put other patients in jeopardy requires conditions which would arise out of incompetent management of the institution."

Lastly, may I mention the expert opinion expressed by no less a person than the president of the National Tuberculosis Association and head of the Henry Phipps Tuberculosis Institute of the University of Pennsylvania, Dr. Charles J. Hatfield, who wrote me as follows: "I am strongly of the opinion that there is no danger whatever to adult patients in the surgical ward of a general hospital from the admission of a tuberculous patient operated upon for thoracoplasty. I am quite willing to have this opinion quoted."

Of the many courteous replies coming from the secretaries of the state boards of health, many of whom are distinguished sanitarians and also tuberculosis experts, I wish to quote a few of the most striking sentences that they added to their reports as personal opinions.

Dr. S. W. Welch, state health officer of Alabama, wrote: "The public phobia in regard to these unfortunate patients is unfortunate, and for the most part groundless."

Dr. F. T. Fahlen, state superintendent of public health of Arizona, wrote: "Five years ago I developed an ugly, acute appendicitis, was operated on, and made a slow recovery. This operation was done in a hospital filled with tuberculous patients and I feel morally certain there were a number of tubercle bacilli floating around all the time. I did not develop tuberculous peritonitis."

Dr. C. W. Garrison, state health officer of Arkansas, wrote: "There are no laws in this state governing the admission of tuberculous patients in surgical wards of general hospitals. Each hospital management regulates the admission and policies. Our great handicap in this state has been to secure adequate hospitalization for emergency surgical cases."

Dr. Tracy R. Love, secretary of the state board of

*Read by invitation before the Eighth Annual Meeting of the American Association for Thoracic Surgery, Washington, D. C., May 5, 1925.

health of Colorado, wrote: "We, in Colorado, feel that the hospitalized patient with tuberculosis is less a menace than the one who is on the street. We have had patients on whom thoracoplasty has been performed, and these patients have then been allowed to have beds in a surgical ward and it was not even deemed necessary to keep screens around them. Furthermore, we do not hesitate to allow patients with active tuberculosis to have ward beds when, for any reason, surgical interference has been necessary."

Dr. William F. King, state health commissioner of Indiana, wrote: "It seems to me that a regulation of this kind is unnecessary and there would be no danger of transmitting tuberculosis to other patients in a ward except through the most reprehensible and criminal carelessness."

Dr. Oscar Dowling, president of the Louisiana state board of health, wrote: "I thoroughly agree with you that there is no valid reason why patients who have been subjected to a thoracoplasty should not be admitted to the surgical ward of any hospital."

Dr. C. F. Kendall, state commissioner of health, Maine, wrote: "I have no hesitation in answering that, in my opinion, there is no danger whatever if a screen is placed between a tuberculous patient and the other patients, and if the attendants remember the precautionary measures that any well trained nurse would be likely to observe."

Dr. James Stewart, state health commissioner of Missouri, wrote: "I personally feel that there is but the remotest danger in the transmission of tuberculosis to other patients and attendants, provided, of course, that the well established principle of hospital ward technic is carried out."

Dr. W. H. Wilson, chief of the Nebraska bureau of health, wrote: "My personal opinion is that tuberculous patients taken into hospital wards to be operated on by thoracoplasty are entirely free from danger to other inmates, provided the proper sanitary precautions are carried out, as they should be in any case of tuberculosis admitted to a general hospital."

Dr. Charles Duncan, secretary of the state board of health of New Hampshire, wrote: "We see no reason why tuberculosis cases of this nature properly handled should not be received in hospitals conducted for surgical cases."

Dr. H. B. Costill, director of health of the state of New Jersey, wrote: "I understand that many of our hospitals are admitting to surgical wards tuberculous patients, and our men claim that they have found no ill results from so doing."

Dr. G. S. Luckett, director of the bureau of public health of New Mexico, wrote: "It seems to me that the demonstration has been rather convincing that the use of cubicles and attention to strict asepsis will prevent cross infections."

Dr. R. G. Leland, chief of the division of hygiene of the state of Ohio, wrote: "I can, without reservation, indorse the opinion of the leading experts in tuberculosis mentioned in your letter, that there is no danger of infection to other patients in a general hospital arising from a tuberculous patient in a surgical ward."

Dr. W. G. Turnbull, deputy secretary of health of Pennsylvania, wrote: "I would consider the passing of such a law or of such a regulation as an admission that we have been teaching erroneous doctrines in the past. If we admitted that we cannot take such care of a tuberculous patient confined in a hospital bed that he will not be a menace to those around him, we are wasting time trying to teach doctrines of this sort to ambulatory patients who are taking care of themselves."

Dr. B. U. Richards, secretary of the Rhode Island state board of health, wrote: "It occurs to me that the term 'room' might be interpreted rather liberally. I am not at all certain, but a part of a ward made separate by the use of screens might legally be interpreted as a room by itself. If the matter should come up for interpretation here in this state, I should certainly try to get away with it."

Dr. James A. Hayne, secretary of the state board of health of South Carolina, wrote: "As far as admitting tuberculous patients operated on by thoracoplasty to the surgical ward of a general hospital, I agree with Dr. Nicoll that the chances for infection are so limited that I do not see why they cannot be admitted to the surgical wards."

Dr. E. L. Bishop, commissioner of public health of Tennessee, wrote: "In my judgment, the danger to other patients would be remote."

Dr. T. B. Beatty, state health commissioner of Utah, wrote: "I cannot conceive of any danger provided ordinary precautions are taken."

Dr. C. A. Harper, state health officer of Wisconsin, wrote: "Such procedures are left to the hospital trustees or governing body. It has been practically the universal practice for a great many years to admit tuberculous patients needing surgical care to any and all medical and surgical hospitals in the state. I know of no hospitals in which there is a bar against such procedures. I can hardly conceive of a remote danger to other patients and attendants by such procedure, especially when ward and hospital technic is conducted according to the well established principles of sanitation."

Dr. G. M. Anderson, state health officer of Wyoming, wrote: "It is my opinion that very little danger arises to the patient's suffering from other diseases when a tuberculous patient who has been operated on by means of extrapleural thoracoplasty is cared for properly in a ward where there are other patients of a nontuberculous character. There can arise very little danger of their contracting tuberculosis."

Instead of giving any further quotations from the tuberculosis experts and the opinions of state health officers, I will quote from a letter received from Dr. Matthias Nicoll, Jr., the distinguished state commissioner of health of New York, as follows: "I need hardly say to you that in my opinion there is but the most remote danger, and one hardly conceivable, of transmitting tuberculosis to other patients and attendants by such a procedure, provided ward technic is conducted according to the well established principles of sanitation."

Dr. Linsly R. Williams, the managing director of the National Tuberculosis Association, writes: "I am heartily in accord with the resolution adopted by the National Tuberculosis Association in 1916 which urged that there be special tuberculosis wards in general hospitals. This we have always felt was a wise and necessary measure for properly caring for cases of tuberculosis. I believe that there is no danger of contracting tuberculosis from patients affected

with that disease in well conducted hospitals or sanatoria. I know, however, that there are many hospitals and sanatoria which are not conducted as well as they should be from the point of view of prophylaxis." To this objection, if it may be considered such, I can only reply that in a badly conducted general hospital there is just as great a danger of propagating other infectious diseases, such as syphilis, gonorrhea, pneumonia, and streptococcus infections, as tuberculosis, and such institutions have no right to exist.

Dr. Bowditch, of Boston, a well known tuberculosis expert, however, does not believe that a movable screen in a corner of a surgical ward is sufficient protection against infection. He then speaks of the unwritten law in Boston that tuberculous patients shall not be admitted in the general hospitals.

According to the information received from Dr. Eugene R. Kelly, the late commissioner of public health, there is no state law in Massachusetts prohibiting the admission of a tuberculous patient operated by thoracoplasty to the surgical ward of a general hospital.

Dr. Joseph H. Pratt, of Boston, wrote me that he had had patients in general surgical hospital wards for thoracoplasty.

Dr. Frank Billings, of Chicago, the well known internist, is most strongly opposed to the idea, and answered as follows: "So far as I know there is no regulation or law in Illinois to prevent the treatment of a patient with pulmonary tuberculosis in a ward with other patients. However, it is not done and I am of the opinion that it would be a dangerous precedent to establish, for while proper precautions would be made in some institutions it is most likely that carelessness would follow in others."

Dr. Billings is mistaken, however, when he says there is no regulation or law in Illinois concerning this matter. Rule 5 in the newly revised Rules and Regulations for the Control of Tuberculosis in the State of Illinois reads as follows:

> "No person suffering from active or open tuberculosis, as defined in Rule 3, shall occupy the same room as a bedchamber or sleeping room with any other person or persons unless such person or persons are suffering also from the same form of tuberculosis. This rule does not however, apply to well adult persons acting as nurse or attendant under the direction of a legally qualified physician."

Dr. George M. Kober, of Washington, is of the opinion that we should not lose sight of the psychic effect of such cases on patients in the wards who are suffering from other diseases or injuries. He considers the decision of the State Board of Charities of New York arrived at several years ago (1909) quite proper, but believes that a properly constructed cubicle with a sheet as door would allay all fears that might arise in the minds of the other patients.

Dr. Willy Meyer was not quite content with my having these expressions from tuberculosis experts but wished me also to tell him how many states in this country have a law similar to this one in New York. Not being able to answer this offhand, I wrote to the state health officers of the forty-eight states and of the District of Columbia. I explained the condition in the state of New York and asked the direct question whether there was any law in their state prohibiting the admission of tuberculous patients operated upon by thoracoplasty to the surgical wards of general hospitals. The commissioners or state health officers of the following states most courteously replied with the decisive answer that there was no law in their states prohibiting a tuberculous patient operated on for no matter what cause to be admitted into the surgical ward of a general hospital: Alabama, Arizona, Arkansas, California, Colorado, Connecticut, Delaware, Georgia, Idaho, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maine, Maryland, Massachusetts, Michigan, Mississippi, Missouri, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, North Carolina, North Dakota, Ohio, Oklahoma, Oregon (except in the city of Portland), Pennsylvania, Rhode Island, South Carolina, South Dakota, Tennessee, Texas, Utah, Vermont, Washington, West Virginia, Wyoming.

All the forty-nine letters addressed to state boards of health were answered. The states of Illinois, Minnesota, and Virginia, the District of Columbia, and the city of Portland, Oregon, are the only ones besides New York reporting the existence of prohibitory laws. It is interesting to note that two of the four states having such antiquated laws have a right to boast also of having in their midst some of the largest surgical centres of the country. I refer to the state of Minnesota, made famous by the great work of the Mayo brothers, and the state of Illinois with its splendid medical schools.

The state of Virginia has the strictest law of all those which prohibit tuberculous patients, who have been operated on, being placed in surgical wards with nontuberculous patients. In this state any person violating the law shall be "deemed guilty of a misdemeanor, and, on conviction thereof, shall be subject to a fine not to exceed fifty dollars for each offense."

A very strong letter favoring such a law came from the state of Minnesota. I quote from this lengthy letter sent to me by the executive secretary of the Minnesota Advisory Commission for Consumptives, Dr. Robinson Bosworth, as follows: "It is our opinion that present regulations requiring that pulmonary tuberculosis cases be placed in rooms or in wards for their exclusive use is wise and reasonable. . . . Patients who are tuberculous should not be placed in rooms or wards containing nontuberculous patients. We see no good reason why an exception should be made of a thoracoplastic case." Yet Dr. A. J. Chesley, the secretary and executive officer of the State Board of Health of Minnesota, says: "My impression is that in spite of the section of the statutes quoted, the opinion of the most advanced medical men is that it is safe to treat tuberculosis cases, of the type mentioned in your letter of March 21st, in the surgical wards of the general hospital."

The thoracic surgeons with whom I communicated are almost unanimously of the same opinion. Dr. Hedblom, however, gave his opinion as follows: "My position in the matter would be that as long as the patient is raising sputum containing the tubercle bacilli, the same rules would apply to him as to a patient who has had no operation." Those of us who are responsible for early diagnosis never wait for its confirmation by the presence of the tubercle bacillus before taking relative precautionary or curative measures. When the physical signs and symp-

toms, aided if possible also by the x rays, strongly indicate the presence of tuberculosis, all precautionary and curative measures are immediately installed. We must also bear in mind that when the patient has a great deal of bronchorrhea, it will often require many specimens before the tubercle bacillus is found. At all events, if we would have to consider the patient operated upon by thoracoplasty as a possible source of infection, not finding the bacillus prior to or immediately after the operation, could not be a decisive factor.

Another objection to admitting tuberculous patients to our general surgical wards comes from the distinguished thoracic surgeon Dr. John Alexander, of Ann Arbor, Mich., now at Saranac Lake, who says: "As a paravertebral thoracoplasty in advanced tuberculosis is a grave operation I feel it incumbent on the hospital not to impose upon any patient accepted for the operation conditions that are unfavorable to him. I consider it an unwise policy to bring a person with far advanced tuberculosis from a country sanatorium and coop him up in screens in a large surgical ward in which the room temperature and ventilation are regulated for those patients accustomed to urban living conditions and in which the usual day and night noises and atmosphere of excitement could be expected only to have a harmful influence upon such a chronic invalid as a tuberculous patient immediately following an operation of the magnitude of thoracoplasty."

Dr. Alexander also says that we must consider the prevalence of phthisiophobia in the laity. I have been in a humble way trying to combat this exaggerated fear of the presence of a consumptive for a quarter of a century and was delighted to have found in our present movement a new weapon against it. In regard to Dr. Alexander's other objection I might say that in our great cities the majority of our patients for thoracoplasty comes from tuberculosis city hospitals where there are no such ideal climatic conditions as those under which Dr. Alexander would desire to have all tuberculous thoracoplastic patients placed. But even should some come from a place in the country, our surgical wards are usually well ventilated and quiet, and a screen near the open window does not exactly mean cooping up a patient who is confined to bed anyway after his operation. Certainly this objection to city air would apply to a private room as well as a ward.

Finally, I should like to ask Dr. Alexander if there are now, as he estimates (1), fifteen thousand persons with pulmonary tuberculosis in the United States for whom surgical intervention is indicated, in how many instances these unfortunate fifteen thousand could be operated on in separate rooms or separate wards under such ideal climatic and sanitary conditions as he feels it incumbent to provide for all patients that have come for thoracoplasty.

Dr. Charles H. Peck, of the Roosevelt Hospital, New York, replied to my letter as follows: "Dr. Willy Meyer has recently brought up the same question to my attention and asked to have our medical board express an opinion on the matter. Their reaction was rather unfavorable to asking for a change in the law. I think the feeling was that the psychic effect upon patients in beds adjacent to that of a pulmonary tuberculosis case would be quite as important as any actual danger which they could probably be protected from. My own feeling is that if these cases are to be admitted to a general surgical ward, they should be, as you suggest, in a separate corner shut off from the general ward by a screen or cubicles (glass partition)."

I am glad indeed to report that in the state of New York, where this latter precaution is observed, we are now permitted, since April 21st, to place tuberculous patients on whom thoracoplasty has been performed in the surgical wards of our general hospitals. How was this accomplished, when up to only a few months ago the New York State Board of Charities absolutely refused to change or modify the law which heretofore made it impossible to admit tuberculous patients into general surgical wards? The credit for this victory belongs primarily to the indefatigable efforts of Dr. Willy Meyer and, next, to the distinguished colleagues who sustained me in my humble opinion, and last but by no means least, to Dr. H. A. Pattison, of the National Tuberculosis Association, to whom I showed all the letters which I had received from sixteen of our leading tuberculosis experts in this country and the numerous letters received from tuberculosis authorities at the head of the State Boards of Health, the vast majority stating emphatically that no danger to an adult nontuberculous patient should arise from the presence of a tuberculous patient operated upon by thoracoplasty in the same ward. Dr. Pattison merely caused copies of all these letters to be made and submitted them, accompanied by a strong letter from himself, to the New York State Board of Charities. A special committee considered all the evidences before them, and the result was a modification of the original law, quite satisfactory to all concerned.

May I say, in answer to the fears expressed by Dr. Peck in regard to the psychic effect upon patients in beds adjacent to the tuberculous patients who have been operated upon, that tactful explanation and the separation by screen or cubicle would allay any apprehension on the part of other patients.

A most interesting situation exists in the state of Oregon, according to the following reply received from Dr. Frederick B. Stricker, the state health officer: "There are no regulations in the state which prohibit the admission of tuberculous patients to hospitals, but in the city of Portland there is a regulation which prohibits the hospitals of that city taking any tuberculous patients. This measure was made some years ago in order to prevent the erection of a state tuberculosis sanatorium in the city of Portland. Many attempts have been made to have this pernicious ordinance removed from the books but so far our efforts have been in vain. Of course, you know that every hospital in this city is taking tuberculous cases and there is no way of stopping them, but still these laws make it possible for hospitals to refuse to take tuberculous patients, which is being done every day in the city of Portland. All the cases that are in the hospitals at the present time are under some other diagnosis. Your interest in this matter is certainly commendable and I trust that you will be able to gather information that will be of value in making it possible for tuberculous patients to enter all hospitals."

(*To be continued*)

The Bassler Pancreatic Efficiency Test in Chronic Cholecystitis*

J. RAYMOND LUTZ, M.D., F.A.C.P.
New York

The treatment of gallbladder disease is a question over which there has been considerable controversy. The surgeons consider gallbladder disease to fall legitimately into their field while the internists would have it in theirs. However, most surgeons agree that not all cases require or are fit for surgery. The internists, on the other hand, usually consider acute, suppurative and gangrenous cholecystitis as well as cholelithiasis conditions which require surgery. This discussion is not concerned, therefore, with these acute cases but with the chronic ones.

The end results of surgery are not always curative. Many of the patients are only partly relieved or not at all. In their reports the surgeons, themselves, admit from ten per cent. to twenty per cent. unimproved cases in addition to the mortality rate from the operation. Only a small percentage of these unimproved cases can be accounted for by recurrence of stones, stone in the ducts, infection of the ducts, adhesions, etc. Furthermore, there are patients who are treated medically for a long time, sometimes for several years, without relief and eventually require operation. On this account, any means which may help us distinguish cases that may be benefited by medical treatment without operation from those which will not and thus save valuable time is very important.

For many years surgeons have noted an enlargement or swelling of the head of the pancreas at operations on the gallbladder. This enlargement or swelling may be due to congestion, inflammation, edema or fibrosis. In the fibrotic cases the damage to the pancreas is permanent and the swelling remains until contraction of the connective tissue takes place. The edematous or inflammatory swelling usually resolves following removal of the gallbladder. Due to the location of the pancreas, however, we have no direct means of determining the presence of this swelling but must rely on indirect evidence, namely, pancreatic function or the examination of its external secretion. The older methods such as examining the stools for food remnants, enzyme activity, nucleus test, etc., are unsatisfactory as they are time consuming and inaccurate. Hypermotility of the alimentary tract and deficiency in absorption render stool examinations unreliable except in cases of gross pathology of the pancreas. Prophylactic or active treatment is then useless. There may be a fairly well marked pancreatic deficiency and yet it may not be evident in the stool as a result of the action of saliva, gastric juice and bacteria. Since the recent renewed interest in this subject by examination of duodenal contents several tests have been suggested. Some of them such as McClure's (1, 2) are too technical and liable to error to be of practical value in a busy office or clinic. To be worth while such a test must be simple, inexpensive, quick, reliable, and the factors of error reduced to a minimum. There have been many conflicting reports concerning the constancy with which the relative concentration of the three pancreatic enzymes occur in the same specimen and in the same individual at different times. In the digestion of fat and protein there are many factors which we do not understand and cannot control. We have no way of determining whether the trypsinogen has been completely activated by enterokinase, nor do we understand the optimum or necessary concentration of various salts and hydrogen ion concentration. In the digestion of fat we have such variables as bile with its changing content of bile salts, buffers, and hydrogen ion concentration, which are very important factors. The third enzyme, amylase, is one that requires no activation and is practically uninfluenced by bile, hydrogen ion concentration within reasonable limits above and below neutral, and its activity is easily determined. Saccharogenic tests, in which the amount of sugar produced by the digestion of starch is estimated, are not reliable because at a given time we have a mixture of dextrins, maltose and glucose which vary greatly in their relative concentration and in their individual reducing power. Alpha, beta, gamma achroodextrin (3) and maltose have twelve per cent, twelve per cent, twenty-eight per cent. and sixty-six per cent. of the reducing power of glucose respectively. For this reason Bassler (4) devised an amyloclastic test, a modification of the one advanced by E. E. Smith (5) for ptyalin, which he presented before the meeting of the American Medical Association in June, 1924.

In his experience he has found that the three enzymes are closely related in their concentration. When one is deficient all are deficient. This conclusion is also borne out histologically as there is but one type of secreting cell present whereas in the gastric tubules there are two types of cells for two secretions but one enzyme. The salivary gland also contains two types of cells but only one enzyme. Therefore, he argues, it is reasonable to assume that the pancreas has a single constant secretion containing the three enzymes and that when the pancreatic cells are injured the three enzymes are equally diminished. On this account the amyloclastic (starch splitting) power can be taken as an index of pancreatic function. This function has agreed with the clinical and pathological findings to a large extent. It is, however, not infallible. There may be extensive disease of the body or tail of the pancreas without an apparent decrease in function. However, any condition which interferes with the free drainage of the main ducts and any disease of the head invariably give evidence of a deficiency in the starch splitting power. Therefore, it is a valuable indirect sign of disease of the pancreatic head. Except in generalized fibrosis of the pancreas, organic disease of the body and tail rarely causes a deficiency; on the other hand, organic or inflammatory disease of the head invariably shows a deficiency whether the condition is transient or permanent.

*Read before the New York Polyclinic Medical School and Hospital Clinical Society, February 1, 1926. From the Department of Gastroenterology, New York Polyclinic Medical School and Hospital.

The symptoms of chronic pancreatitis may simulate those of chronic cholecystitis except for colic and jaundice. As a matter of fact, two years' experience with the test suggests that the socalled reflex gastric symptoms are more often due to an associated pancreatitis and gastritis than to a true reflex.

Every case of chronic cholecystitis should have a pancreatic test done by the internist or surgeon. If the pancreatic function is normal (ten to twenty Bassler units) medical treatment should be given a thorough trial unless the patient has frequent severe attacks of colic, in which instance the physician should be guided by his clinical judgment. If a low pancreatic efficiency is found (six units or less) and confirmed by a second test the gallbladder should be removed at once as it indicates secondary disease of the head of the pancreas which may progress, by delay, to a permanent fibrosis. The lower the function, the more likely is the pancreas to have undergone fibrosis. In the majority of unimproved postoperative cases a deficiency existed before the operation, due to advanced fibrosis. In these cases removal of the gallbladder will but slightly help the pancreatic condition. In the cases where the pancreatic deficiency is due to congestion or edema, removal of the gallbladder is usually shortly followed by a marked improvement in the symptomatology and the pancreatic function. Cases under medical treatment should have frequent tests made. A steadily decreasing function or one that remains low after several weeks of treatment is an indication for cholecystectomy. Postoperatively, the test is of value for prognosis and treatment.

The question of what to do for individuals with pancreatic deficiency both preoperative and postoperative is one that up to the present has not been satisfactorily solved. Many patients do well on pancreatic powder in large doses, one to three grams with soda bicarbonate. Others improve on feedings of freshly pickled pancreas at meals. Some patients show improvement as a result of a series of Lyon nonsurgical biliary drainages or the use of magnesium sulphate daily by mouth.

CONCLUSIONS

1. The Bassler pancreatic efficiency test is simple, easy to perform, accurate enough for clinical interpretation and inexpensive.
2. When low it usually indicates disease of the head of the pancreas.
3. By determining the condition of the pancreas it gives an indication for medical or surgical treatment in chronic cholecystitis.
4. It is of diagnostic and prognostic value, postoperatively.

Renal Function Tests in General Practice*

H. LEON JAMESON, M.D.
Philadelphia

In recent years the study of the functional activities of the various vital organs has attracted, in an increasing degree, the attention of both laboratory workers and clinicians. Function tests of the liver, pancreas, thyroid, adrenals, pituitary and other digestive and endocrine glands have become fertile fields for research. Mackenzie and others have stressed the importance of estimating the efficiency of the circulatory system from both diagnostic and prognostic standpoints. The response of the myocardium to measured exertion and other heart function tests have become almost indispensable in cardiac practice and life insurance companies now require them in all suspicious cases. Even the mental processes are being tested by the psychologist with almost mathematical precision. No less attention has been devoted to the study of renal function.

It has long been recognized that there are types of nephritis in which routine urine analysis has failed to give diagnostic help, especially in early cases. For example, we know that many instances of interstitial nephritis and renal sclerosis, even in moderately advanced stages, fail to show either albumin or casts in the urine. Moreover, there are conditions in which albuminuria and even casts may be present without significant renal lesions or impairment of function. In such cases the value of renal function studies can scarcely be overestimated. On the other hand, in the acute forms and in the comparatively rare chronic nephritis with edema, the diagnosis is usually readily made without function tests even in their incipiency. Therefore, from a diagnostic viewpoint, at least, functional estimation is of most value in those chronic varieties, in which albumin and casts are frequently absent and which sooner or later are characterized by defective nitrogenous elimination.

The tests of kidney function advocated have been many and various, indicating that none is entirely satisfactory. Some of these offer technical difficulties and can only be used upon hospital patients, or at least by those having access to well equipped laboratories. On the other hand, among the most valuable and enlightening are some which are simple and can be readily and conveniently used by the general practitioner.

While function studies depending upon the ability of the kidneys to excrete foreign test substances, notably phenolsulphonephthalein, are helpful in some instances, they are rather technical and are not suitable for private practice. Moreover, in the presence

*Read before the Philadelphia County Medical Society, April 14, 1926.

of cardiac inefficiency or edema, intravenous administration is necessary to obtain anything approaching reliable results. The collection of blood for chemical studies is not a complicated procedure and reliable laboratories are available to most practitioners. However, the estimation of nitrogenous retention in the blood is of doubtful value as an early diagnostic test, although it is helpful in more advanced cases and often gives much prognostic information.

Comparison of urea concentration in the blood and urine offers insurmountable difficulties in extramural practice, and, moreover, the method is open to many fallacies. For these reasons the above tests are not here advised. At least their use should be restricted to those cases in which the more simple procedures reveal kidney insufficiency and seem to indicate more elaborate study.

Certain clinical findings give rise to suspicion of renal involvement. In addition to the more or less marked toxic symptoms, nocturia, arteriosclerosis, hypertension, secondary anemia, failing vision, etc., unless otherwise explained, call for careful and repeated examinations of the urine. Should these prove negative in their results, the renal functions should be investigated. In routine urine examinations it is advisable to analyze both morning and evening specimens. Urine obtained after the stress of daily metabolic activity often shows abnormalities which are absent in morning samples. Moreover, comparison of the morning and evening specific gravities is advantageous. Should these both be low, lack of flexibility and concentrating capacity on the part of the kidneys may be suspected.

THE TWO HOUR TEST

This fixation of the specific gravity can be more accurately determined by Mosenthal's (1) modification of the Hedinger and Schlayer (2) test—the so-called two hour test of renal function. It depends upon comparison of the volume and the specific gravity of two hourly specimens throughout the day and a single specimen during the night, in addition to estimation of the nitrogen and sodium chloride output. Originally a "high protein diet" containing 13.4 gm. of nitrogen, 8.5 gm. of salt and 1,760 c. c. of fluid was advocated. As the chief results agree regardless of the diet, this valuable test may be simplified and adapted to general use. When impracticable to employ this standard diet, the patient can have three full meals taken at 8 a. m., 12 noon and 5 p. m., the socalled normal diet, using a pint of fluid with each meal. No food or fluids should be taken between the meals or during the night.

The bladder is emptied at 8 a. m. and the urine collected at two hourly intervals until 8 p. m. All urine voided between 8 p. m. and 8 a. m. is collected in one quantity. Punctual collecting of specimens is essential and it is important that three hours should elapse between the evening meal and the beginning of the night period. The patient should be given properly labeled bottles for the six day and single night specimens.

Normal renal function is characterized by decided variations in the specific gravity of the specimens, reaching nine or more points if a high protein diet be used. The maximum concentration is usually obtained in the night urine, which should have a specific gravity of 1,020 or over. The volume of the urine voided during the night should not exceed 750 c. c. and should be less than the day output. Lowering of the maximum specific gravity and increased night volume of urine are said to be the most constant and reliable indications of renal impairment. "The nephritic kidney tends to secrete a urine of persistently low specific gravity," therefore fixation at a low point is suggestive of disease. Estimation of nitrogen and sodium chloride percentages is not essential and may be omitted, although lowered output of salt and nitrogen also points to hypofunction.

The Mosenthal test is one of the most reliable of the procedures for estimating the functional condition of the kidneys. It detects early renal involvement and possesses the advantage of simplicity, hence I feel that it is worthy of more extended application, especially in general practice.

THE CONCENTRATION DIURESIS TEST

Another helpful method of examining renal function is the concentration diuresis test, which determines the ability of the kidneys to excrete both concentrated and diluted urines. The method is not complicated and obviates the necessity of collecting two hour specimens; it also eliminates any question of standard diets. The test can readily be carried out by the busy general practitioner with the cooperation of any patient of average intelligence.

The ability to excrete urine of high specific gravity is impaired early in nephritis. In such cases, as a rule, the elimination of water is delayed. These important functions can be tested at the same examination. We first endeavor to force the kidney to excrete a concentrated urine following a twelve hour fast, after which the diuretic effect of a large quantity of water is noted. The simple procedure is as follows:

After the usual evening meal at 6 p. m., the patient abstains from food and water throughout the night and the bladder is emptied as completely as possible between six and seven o'clock. During the next three hours the fast and thirst are continued and at the exact expiration of this period the patient voids again. This three hour "concentration" specimen is saved for examination.

Immediately after voiding the patient drinks two and one half litres of water during the succeeding one and one half hours. This is a less difficult task than it would seem to be, especially if the water be not too cold. Least inconvenience is probably experienced if one litre be taken at the beginning of the diuresis test and a half litre at half hour intervals thereafter. During this three hour period all urine is collected. Normally, the volume of the concentration specimen varies between 50 and 200 c. c., while the "diuresis" urine exceeds 1,000 c. c., averaging about 1,500 c. c., or sixty per cent. of the fluids ingested. The specific gravity of these specimens should be carefully tested at room temperature. The concentration specimen should exceed 1021, while the diuresis sample should be 1003, or lower. Olmsted (3) asserts that in addition to detecting early renal disease, this test helps us to appreciate the degree of the cardiac factor where both heart and kidney are involved. "A good kidney and a poor heart will show a good concentration and normal specific gravity, but a very limited ability to 'diurese' water."

THE UREA CONCENTRATION TEST

The kidneys have the power of concentrating urea and other nitrogenous bodies to a remarkable degree. Normal urine contains from sixty to eighty or more times as much urea to a given volume as does the blood. This ability to concentrate urea is impaired early in nephritis, and advantage of this fact has been taken by MacLean and de Wesselow, who introduced the urea concentration test. This simple test indicates "lesions of a much slighter degree than are detected by estimation of blood urea." Moreover, it requires no manipulative skill other than the estimation of the urea in the urine. This can be done by any physician using one of the modifications of the hypobromite method. The Doremus-Heinz ureometer simpifies this examination. However, if the physician prefers, the specimen could be sent to a laboratory.

As the test should be preceded by a fluid fast of twelve or more hours, to prevent, or at least minimize, diuresis, it should be performed in the morning, preferably following a rather dry breakfast. The patient should be instructed to empty the bladder, after which fifteen grams of urea dissolved in 100 c. c. of water are ingested. The somewhat unpleasant metallic taste of urea can be disguised by a few drops of tincture of orange or by orange juice. Specimens of the urine are obtained at the expiration of one and two hours. Rarely the urea produces diuresis, which is more apt to dilute the urine secreted during the first hour, hence it is better to examine the second specimen only, which should not exceed four ounces in quantity. A percentage of urea above two is indicative of fairly efficient function; the higher the concentration the more favorable being the result. On the other hand, percentages less than two show functional impairment.

This test is used extensively in England, and has given satisfactory results. While it lacks absolute accuracy owing to the slightly varying rate of absorption of urea from the intestines, which depends somewhat upon the emptying time of the stomach, this detracts little from its value as has been proven in thousands of cases.

Other tests of kidney function might be mentioned, but it is felt that those which have been considered are among the most reliable and are well suited for use in general practice. Renal function tests should be resorted to more frequently by the general practitioner in an attempt to diagnose incipient disease, for the successful management of nephritic conditions depends largely upon early recognition. Lastly, under no circumstances should these or any other laboratory methods replace a thorough clinical examination.

Stomatology in France in 1925

JULIEN TELLIER, M.D.
Lyons, France

This article has a modest and unpretentious aim: that of reviewing as briefly as possible what French stomatologists have been doing for the past few months (October, 1924, to October, 1925) and of deducing some remarks of a general order leaving aside all questions of professional politics. These are in general some reminiscences and communications presented, either before the Society of Stomatology of Paris, whose president is Dr. Herpin, or before the Annual Congress of Stomatology of 1924, whose president was Dr. Chompret, president of the A. S. I., and in 1925 presided over by the writer of this article; the next congress will be presided over by Dr. Sauvez. These remarks have been published for the most part in the *Revue de Stomatologie*, directed by Dr. Nogué, sometimes in other professional journals (the *Semaine Dentaire* for instance). The special theoretical and technical material is vouched for by the Ecole Française de Stomatologie, whose director is Dr. Bozo.

A list of the principal contributions follows:

A. *Normal anatomy.*—Professor Retterer: Researches on the structure and evolution of teeth of the wild boar. Herpin: Note on the evolution of dentine and enamel. Duchange: Study of the topographic anatomy of the perimaxillary regions (personal procedure for regional anesthesia).

B. *Pathological anatomy.*—Delater and Bercher: Tumoral complications of septic paradental foci. Crocquefer: Paradental granules and cysts. Retterer: Structure of the gum in some pathological conditions.

C. *Physiology.*—Marcel Darcissac: Mandibular physiology and artificial teeth (important work which has led its author to the construction of a new physiological articulator of an ingenious nature).

D. *Dental caries.*—Faugin Fayolle: Dental caries: problems, facts, hypotheses. Jules Ferrier: Deep lying causes of dental caries: heredity, constitution; dental caries and morbid predispositions. J. Tellier, Romey and Beyssac: Teeth of the tuberculous: experimental, clinical and therapeutic remarks.

E. *Alveodental pyorrheas: pathogenesis and treatment.*—Béliard: The retention prothesis; prothetic treatment of pyorrhea (1924); treatment of pyorrhea by retention bridges (1925). Rousseau-Decelle: General remarks on the treatment of alveolar pyorrhea. Fichot: Medical and vaccinal treatment. Monier: Surgical treatment. Psaume: Treatment through physical agents. Béal: Remarks on the treatment of alveolar pyorrhea. Lebedinsky: The grand

pyorrheal syndromes. Chateau: Mechanical theory of the progressive alteration of a pyorrheal tooth; therapeutic consequences; treatment by prothesis and supraocclusion. Duchange: Note on local vaccination for alveolar pyorrhea. Darcissac and Legrain: Vaccinotherapy for alveolar pyorrhea through a culture fixed in the vaccination incision. Saidman: Use of ultraviolet ray lamps in the treatment of the pyorrheas.

The papers presented at the Congress of Stomatology of 1924 and of 1925 on the treatment of alveolar pyorrhea were all noteworthy and the discussions assumed a fullness indicative of their importance. Two of these, however, warrant our special attention. First, Béliard's report, presented in 1924 and discussed in 1925, and accompanied with a demonstration by the author of retention bridges and their effects that merits admiration. But it is the report of Fichot, of Clermont Ferrand, that to my mind shows the best work. It is at once original, and also truly critical beyond question.

It seems to be the belief in foreign lands, and particularly in America (1), that the vaccinal treatment of alveolar pyorrhea has been accepted and is employed by the majority of French practitioners, and considered as the treatment indicated in the great proportion of cases, and ordinarily, if not always, followed with favorable results. This is not the case. Even if it is so in the case of several thousand odontologies free from infection, all true stomatologists are far from accepting it as conclusive.

The chief merit of the work of Fichot is that, on the basis of the most perfect scientific considerations possible, he discusses and presents individual indications or those related to all the therapeutic procedures, medical or vaccinal, and shows us once more that the treatment of alveolar pyorrhea is much more a question of medical diagnosis than of technical procedures whatever they may be.

F. *General pathology.*—Rousseau-Ducelle: Remarks on the probable rôle of the sympathetic endocrine system in buccodental pathology. Ureteral and ovarian influences. Frey: Rachitism; maxillaries and teeth. Watry: Rachitism and maxillar malformations (clinical study). J. Tellier: The periodontium; mixed tissue in conjunction with epithelial conjunctivitis. Anatomical, clinical and therapeutic aspects.

G. *Studies on sepsis of the mouth and teeth and focal infections.*—Worms and Becher: Ocular affections of dental origin. (An important work, well conceived and studied, with very interesting conclusions as to the pathogenesis of these symptoms, followed by their treatment). Béhaigue: Major neuralgias of dental origin. J. Tellier: Buccodental sepsis and endocarditis. Lebidinsky: Pyophagia—complications and treatment.

H. *Special pathology.*—Bercher and Krivine: Lower subcondyle fracture. Chompret and l'Hirondel: Migratory abscess of the lower vestibule (or vesicle?) or buccomaxillar abscess. l'Hirondel: Actinomycosis of the face. Merville: Osteomyelitis of the lower maxillary. Thésée: Two cases of osteomyelitis of the lower maxillary in the region of the chin, resembling an infection of fusospirilliform symbiosis. Chompret: A case of molar temporarily enclosed. Herpin: Concerning inferior prognathism. Dufougère: Gangrene of the soft parts following the use of certain translucent cements perhaps to be avoided? Gournouec: A case of elephantiasis of the lip. Thésée: Double epithelioma of the lower lip in a young man. Troude and Pacaud: A case of epithelioconjunctival epulis. Bloch: Supernumerary teeth. Thibault: Note on a case of aphthous stomatitis. Ginestet: Ulceromembranous traumatic stomatitis. Lacronique: Gingivoalveolar trophoinfectious reabsorption.

Let us emphasize also: Raison: Pathology of the salivary glands; congenital absence of the parotids; malformation of hereditary syphilitic origin. Gougerot: Tuberculosis and elephantiasic nocardiosis of the mouth. Duchange: Fractures of the jaws in practice.

I. *Surgery of the mouth.*—Monier and Nodine (of London). Boisson and Polus: Surgical treatment of alveolar pyorrhea. Leclerc and Rodier: Alveolar excisions, presented by surgeons from the Paris hospitals. Veau: Harelip: technic, statistics, results (excellent paper). Moure: The principles of tubular grafts in the repair of the lips and of the chin (splendid results of surgical reconstructions of gross mutilations). Dufourmentel and Darcissac: Deformed noses and their surgical and prothetic treatment; total reconstruction of the lower maxillary. Dufourmentel: Recent observations on temporal maxillary ankylosis, secondary to infections of dental origin.

We owe special thanks to Dr. Herpin, president of the Society of Stomatology, for having interested leaders in general surgery in the works of our professional organization.

J. *Orthodontia.*—Izard: Transverse maxillary expansion in dentofacial orthopedics; (personal work and criticisms of a remarkable nature). P. Robin: Eumorphic treatment (presentation of a large number of patients; remarkable results following the use of the method of the author). James Quinteroc: Dislacement of roots in the vestibular sense in the course of dentofacial orthopedic treatments, with presentation of models of excellent results.

K. *Protheses.*—Guilly and l'Hirondel: Retention with complete appliances. Château: Alveolar pyorrhea. Béliard: Conception of the fixed dental prothesis according to the laws of mechanics and of clinical facts. Marcel Darcissac: Surgery of the mouth and physiology, rational mounting of artificial teeth by the physiological method; contribution to surgical prothesis of the medial portion of the face. *Ibid.* with Flipmann and Dubois: Demonstration of dental and maxillofacial prothesis (presentation of patients and of apparatus—fine results of the ingenuity of Dr. Darcissac and his collaborators).

L. *Experimental medicine.*—Kritchewsky and Seguin: Unity of buccal spirochetes; first researches on chronic infections of the soft parts and of the apex. A work of the same authors entitled the Importance of Acidophilous Bacteria in Paradental Affections should have been presented at the Congress of 1925, but Dr. Kritchewsky died during the Congress. We here pay tribute to his memory. Laudète and Mayoral: Bacteriotherapy in odontostomatology.

M. *General and special therapy.*—Treatment of alveolar pyorrhea: See above. Ruppe: General re-

view of the treatment of penetrating caries. Pitsch: Treatment of infected teeth. Lacronique: Remarks on the surgical treatment of infectious paradental foci. J. Tellier and Beyssac: Preventive odontomy. Duquet: Late reimplantation. Ginestet: Two cases of persistent hemorrhage with dental evulsions; treatment and etiology. Faugin Fayolle: Rapid treatment with bismuth. Duchange: Trepanning for apical resection; note on vaccinotherapy for buccal and paradental affections; fracture of the jaws in practice (Admirable book, the most important in existence on this subject). Lemaître: Fixed drainage for cancers of the jaws at their outset. Dieulafé: Treatment of epithelioma of the buccal cavity with radium.

N. *Anesthesia.*—Bercher: Studies of regional anesthesia; demonstrations of anesthesia of the masseter muscle. Puig: On masseterine anesthesia. Duchange: Note on the use of sulphate of magnesium in local anesthesia; anesthesia of the trunk of the inferior maxillary nerve.

O. *Physical procedures; technic.*—Cièszinski: Exact intrabuccal radiography of the teeth. Bretton: Presentation of radiographs. Husnot: Remarks on amalgams.

P. *History.*—Bloch: Taveau. Boissier: Dental science in old Castile in the middle of the sixteenth century. Two amusing, witty essays, and at the same time suggestive and instructive as to historical events, men and theories in our profession.

Q. *Education.*—M. Morineau showed an interesting film on the preparation of cavities in caries. Numerous demonstrations were given in the course of the Congress at the French School of Stomatology and in the stomatological services of the Paris hospitals, particularly by Pouroy, chief of the maxillofacial service of the Military Government of Paris. At the School of Stomatology, the faithful librarians of the school and of the Society of Stomatology, Bloch and J. Puig, bore witness to their tireless devotion by putting at the disposition of visitors professional works and anatomical and pathological collections, to the great benefit and instruction of all. May we be permitted to add that the problems of the general tendencies of our profession have also been studied in an Assembly (Syndicate of French Stomatological Physicians), of which the presidents were in 1924 and 1925 respectively P. E. Gires and W. Pietkicwicz.

The simple conning of this list suffices to show the tendencies of stomatology in France. It is interesting itself more and more in everything that touches its anatomical and clinical domain, and forcing itself to put in practice methods of work that connect all the medical specialties with general medicine and which consist, as has been indicated by Professor H. Claude of Paris in regard to a specialty other than ours: 1. In applying to stomatology methods of observation and research used in general medicine. 2. In establishing on broad biologic standards new conceptions of buccodental maladies and their complications. 3. In developing standards of general and special hygiene so that new ideas may be the results of all these conditions.

It would be easy, if our space were not limited, to cite numerous typical applications. Apropos of the treatment of the dental caries (and the word should be used in a plural rather than in a singular sense), indications should be more and more based on medical clinical observations and experimentation. Each case of caries is individual; why do one or more teeth become affected with caries? A local and general diagnosis should be made for each patient. The procedures in disinfecting the cavities in caries, the length of the treatment, are variable according to the nature of the species of bacteria found (aerobic or anaerobic). Each case demands a special local treatment, a particular general treatment.

The same rules must apply to the treatment of alveolar pyorrhea—to the precautions which should be taken, from the stomatological point of view, before major surgical intervention,—to all the cases of orthodontia, where the esthetic result can be only a secondary consideration—to the discussion of prothesitic indications—in the choice of therapeutic procedures and the technic to use with patients afflicted with affections of the circulatory, respiratory systems, etc.

In brief, the general tendency seems to be to augment more and more intensively general medical instruction, in order to gain in the first place, and then to develop what we may call, speaking properly, "a stomatological state of mind," which we will define in a few concise sentences; it is well understood that the stomatologist must possess a special technic in a very high degree; but the acquisition of this technic is not the end of his professional education, it is only a means, and not an end in itself. To define this "stomatological state of mind" let us repeat here what we said in opening the Congress of Stomatology in 1925 at Paris: "It is a point of view, a way of seeing, a special way of thinking which makes us always on the watch to attach the object of our labors to general medicine, to utilize appropriate technical methods; it is a mental attitude that makes us think in a particular fashion, as one thinks physiologically, anatomically, pathologically. To think stomatologically is to think as a physician who examines the problems which present themselves to him with mental habits with which he is impregnated through his medical habits;" to study the relations that exist or can exist between these problems and their possible consequences in the domain of medical, hygienic or social knowledge; when we have the stomatological state of mind, "the practice of our profession takes in our eyes a wholly new aspect; knowledge gives assurance and confidence. We see from then on, in all the acts of our professional life, the medical standard everywhere imminent, but invisible to the eyes of the uninitiated. If we think stomatologically, then medically, everything is related in our minds, and the phenomena which we observe in our daily professional practice are explained."

It is through the acquisition alone of the stomatological point of view that we shall contribute to the development of prophylactic hygiene and preventive medicine. (Charles H. Mayo). Objection may be made that the ideal is intimate collaboration, the symbiosis of physician and stomatologist. This is perhaps true elsewhere than in France, although I am not at all convinced. But with us the education in

stomatology of the physician is practically nil, and it will be a long time before it will be otherwise. It is necessary, in order that the stomatologist do his social duty as we understand it,—it is necessary that he have a medical education, if not more, at least equally as extensive as any other physician; it is necessary that he be permeated at one and the same time with the stomatological and the medical point of view in the highest degree in order to study and bring into relationship the numerous and agonizing affections of the mouth and teeth with general pathology.

Treatment of Diabetes—Present Status Outlining a Rational Regimen

A. I. RUBENSTONE, M.D.

Philadelphia, Pa.

With the addition of insulin to the medical armamentarium there has been added one of the most valuable and specific measures in the treatment of diabetes. Though it had long been known that the hormone secreted by the islands of Langerhans of the pancreas was the internal secretion that governed carbohydrate metabolism, and means of obtaining it had engaged the attention of researchers for the past thirty years, the apparently insurmountable difficulty of separating it from the toxic alkaline external secretion of the pancreas was accomplished by Banting and Best in a series of brilliant experiments that do not admit of discussion here.

Briefly, insulin, as the hormone was named by the discoverers, is the active principle of the secretions of the islands of Langerhans of the pancreas in living animals. Small quantities have also been found in other organs and fluids of the animal body, and its recent demonstration in plant life leads to the belief that it has a widespread distribution through both the animal and vegetable kingdom. At first the product experimentally was crude and only obtained in small quantities. As a result of intensive experimentation, insulin today is a refined product produced in large quantities from the glands of adult slaughterhouse animals and its dose standardized accurately by biological assay. It is a clear, colorless, watery solution, sterile, put up in ampoules of five c.c. each, each c.c. containing ten or twenty units as indicated on the label.

In order to produce an appreciable physiological effect it must be introduced parenterally. If given by mouth, it is largely destroyed by the digestive juices before its absorption takes place and, so far, no means to overcome this disadvantage are in sight. This accounts for the failures obtained in pancreatic extract or whole gland by mouth. Likewise, it is impotent when given by nasal spray or by rectum. It therefore can be administered intravenously, or subcutaneously. The intravenous route is chosen only when rapid action is desired, as in severe acidosis or coma. By way of the blood stream its action is fleeting. The subcutaneous route is the one of choice, thus the extract is slowly absorbed and acts more slowly, and more nearly approximates the normal absorption in health.

The physiological effect following the introduction of insulin into the system is the prompt utilization and distribution of carbohydrate in the system as evidenced by blood sugar reduction, with a corresponding increase in the respiratory quotient and a reduction or disappearance of the urinary sugar. The disappearance of the sugar is accounted for by a marked increase in liver and heart glycogen. This carbohydrate stabilization is peculiar not only to diabetics, for insulin also controls the hyperglycemia in animals caused by asphyxia, carbon dioxide poisoning, injection of adrenalin and that due to ether anesthesia experimentally.

It has also been ascertained that the organs, notably the liver, show a decrease in fatty acid content following the injections of insulin into the diabetic patients or animals rendered diabetic. There is a coincidental amelioration of the major symptoms of the disease and the patient becomes subjectively optimistic and in a state of wellbeing. Where edema exists it rapidly disappears, probably due to the equilibration of the water balance of the system. The tendency to acidosis and coma are likewise overcome.

Given in overdose, the symptoms are characteristic and sometimes alarming, even causing death unless the specific antidote, sugar, is promptly administered. The typical reaction is initiated in one half to three hours after the overdose administration. As the blood sugar falls to a low level (usually below eighty mgs.) the patient experiences a sense of weakness and drowsiness; perspiration and muscle tremors set in. There is hyperpnea with a full bounding pulse. In the severer reactions this may be followed by delirium, coma, cardiac depression and death. This train of untoward symptoms is known as the hypoglycemic reaction and can be readily overcome by prompt administration of sugar by mouth in assimilable form. When the patient is already unconscious, while intravenous sugar, two hundred or three hundred c. c. of a five per cent. solution, is being prepared, one c. c. of adrenalin, one to one thousand solution, should be injected intramuscularly. This helps to mobilize the sugar from other tissues and is the only other remedy that aids in overcoming the hyperglycemic reaction.

The dose of insulin is governed by physiological assay. Arbitrarily, the discoverers propose to call the unit a third of the material necessary to cause convulsions by hypoglycemia in a two thousand gram rabbit previously fasted for twenty-four hours. It has been established that one unit will account for one to two grams of sugar in the diabetic. Our figures,

especially in one case of a severe diabetic, would tend to show that this is a variable quantity so that sometimes a single unit will account for no more than a half gram of sugar.

Therapeutically, insulin, injected subcutaneously, will be slowly absorbed into the blood stream and act for a period of six to twelve hours, when it is either entirely neutralized or excreted by the kidneys. Thus, if one watches the blood sugar curve, it is interesting to note that its maximum action is reached within three or four hours after administration and then gradually as its effect wears off the blood sugar begins to rise and again within twelve hours reaches the same level as before insulin administration. It is obvious then that one or more injections of the extract is necessary a day when insulin is added to the diabetic regimen. Too large a single dose will surely bring on a hypoglycemic reaction. It is therefore important to balance the quantity of insulin injected with the food ingested.

An erroneous belief has arisen among some since the discovery of insulin that dietary measures were no longer necessary and that injections of the extract would take care of the diabetic disorder. I cannot too strongly emphasize the uselessness or danger of such negligence. It is probably fortunate that insulin was discovered after brilliant researches such as conducted in this country by Allen, Joslin, Wilder, Schaefer, and others, established definitely the relationship of protein and fat to the diabetic disorder and the harmfulness of total overfeeding in this disease and, what is most important, the relationship of focal infection to diabetes.

Thus it has been shown that fifty-eight per cent. of the protein intake can be used as glucose by the body, that protein causes an increase in metabolism because of its specific dynamic action. In a large quantity it embarrasses the organism in its attempt to utilize sugar. The determination of the nitrogen balance is therefore important in diabetes. Similarly, to avoid acid intoxication, the fat and carbohydrate intake must be carefully gauged to avoid incomplete fat combustion and a resulting production of ketones. As to overfeeding generally, an added burden to an already inadequate pancreas will further embarrass it. There is no excuse at present for overfeeding when definite caloric requirements have been established and are available for all adults.

Using insulin in diabetes is mimicking the normal pancreatic function. In the healthy individual the blood picks up insulin from the islands of Langerhans in proportion to meet the needs of the food intake. Insulin is meted out to the system therefore slowly and if we are to imitate Nature in administering insulin, it at best will be crude, with all the precautions possible. But if these known precautions, viz., the quality and quantity of diet ingested and the relationship to insulin administration, are disregarded, either serious reactions or little result will be achieved. The use of insulin in properly managed diabetics therefore will result in reestablishing a normal metabolism and consequent cessation of further tissue degeneration, with return to normal body function both subjectively and objectively, and obviously will result in resting the diseased pancreas in allowing it to recuperate as fully as possible.

Insulin has a specific value, therefore, in all cases of diabetes, but not all patients require insulin. The use of insulin is indicated in the following four classes of diabetics:

1. It is imperative in all cases complicated by acidosis and coma, by infections, intercurrent diseases, and in contemplated surgical procedures.

2. In severe diabetes with low sugar tolerance where reduction, if at all, of the hyperglycemia can only be accomplished by very low diet and frequent fasts and low body weight with physical incapacity.

3. In the moderately severe cases the use of the extract is optional where dietary restriction, plus rest, brings the blood sugar curve down and dispels glycosuria. The advantages of insulin in these cases are that it reduces the rest period and allows of an easier pancreatic recuperation when the burden is removed from that organ.

4. In the mild cases, where the blood sugar is slightly elevated above the normal, the symptomatology and elevation of blood sugar can be easily relieved by proper dietary restriction without the use of insulin. This is especially true of fat diabetics.

AMOUNT AND FREQUENCY OF INJECTIONS

The first few subcutaneous injections may give the patient a slight local, stinging pain; later the patient accommodates himself and rarely complains. An ordinary hypodermic syringe and needle with the usual precautions for sterility are all that is necessary. Many patients learn to give themselves the injections and this simplifies the administration. The number of units a day necessary for any one patient is a variable quantity entirely dependent on the sugar tolerance and diet. Thirty to forty units a day usually suffice to permit an assimilation of about 2,500 calories, provided the diet is properly proportioned.

It is wise, in order to avoid reaction due to individual susceptibility to the extract, to begin with small doses and gradually increase them. After the patient has been established on insulin it is well to ascertain his sugar tolerance from time to time and, as the pancreatic function begins to return, the dose is gradually diminished and the number of injections per day lessened so that in many cases where the pancreatic pathology is not already far advanced, we can hope eventually for enough return of function normally so that the patient may eventually need no more insulin injections.

Insulin is usually administered about twenty minutes before meals and, if a single dose a day is to be given, preferably before breakfast. The advantage of the morning dose is its continued action through the active part of the patient's day. A large single dose obviously cannot take the place of two or three small ones because of the danger of hypoglycemic reaction. Administration before bedtime should be avoided because when a reaction occurs during sleep it may not be recognized and thus endanger the patient's life. When more than one dose of insulin is to be used per day, the day's caloric intake of diet should be evenly proportioned to meet the injections otherwise a hypoglycemic reaction might result if too little food is given at any one meal to balance the insulin injected.

At the Mt. Sinai Hospital we have established a rational plan of diabetic management so that, on admission, a patient can be immediately cared for by

any house physician. In order to establish a working routine it is necessary:

1. To establish a series of wellbalanced diets so that there would be a balance between the carbohydrates and the fat in the twenty-four hour intake to avoid the possibility of acidosis; to this end we established five diets, the first of about 400 calories, the second 800 calories, the third 1,200 calories, the fourth 1,600 calories, and the fifth 2,000 calories. The foods are so arranged quantitatively that only the ordinary kitchen utensils are necessary to measure them, the kind and quantity of foods plainly stated so that no knowledge of dietetics is necessary to understand how much food and the kind of food is to be taken for the day.

2. For example, diet 3 detailed below, typifies its simplicity and the ease with which it can be carried out in any kitchen. Aside from these routine diets an instruction sheet is also provided which gives the patient a greater variety of foods having the same caloric value, and also detailed recipes for making diabetic preparations. In this sheet the patient is also informed of the food values of articles of diet that are usually present in a household.

DIABETIC DIET SHEET 3

Carbohydrates, 60; protein, 45; fat, 90; calories, 1,230; sugar value, 96; ketogenic antiketogenic ratio, 1 to 1.2.

Breakfast: One half grapefruit, one half cup (scant) cooked oatmeal, one egg, one and one half tablespoonsful butter, three tablespoonsful sweet cream, bran biscuit, coffee with saccharine.

Dinner: Broth (any quantity), two cups five per cent. vegetables, one half cup ten per cent. vegetables, one and one half ounces cooked meat, one slice (thin) Kolb's bread, two tablespoonsful butter, one tablespoonful sweet cream, coffee or tea with saccharine.

Supper: One cup five per cent. vegetables, one cup 10 per cent vegetables, one egg, one Diaprotein biscuit, one tablespoonful butter, one tablespoonful sweet cream, coffee or tea with saccharine.

ROUTINE TREATMENT IN THE HOSPITAL

1. On admission to the Mt. Sinai Hospital the patient is thoroughly examined to determine complications such as acidosis and intercurrent disease.

2. All possible foci of infection sought for with a view to eradication.

3. The patient is placed on one of our basic caloric maintenance diets (usually 800 calories, diet 2, or 1,200 calories, diet 3).

4. Meanwhile the patient's metabolism is studied from a laboratory viewpoint as well as a routine laboratory measure.

5. His tolerance for carbohydrates is then established by estimating the amount of glucose excreted in the urine while on diet. If it is found after three or four days on a given diet that the carbohydrate tolerance is lower than the individual need of the body and the patient already is a little below weight, then his basal diet that he was placed on is continued and insulin is added to the régime to make up for the glucose thrown out in the urine; for example, figuring that one unit of insulin roughly will take care of two gms. of sugar, the patient is then placed on one unit of insulin for every two gms. of sugar thrown out in the urine. This is continued for several days and the insulin either reduced or increased in order to cover the basic diet that the patient is ingesting.

Blood sugar estimation should be done once a day or once every other day before breakfast until the blood sugar constantly remains within the normal range. The dose of insulin is then gradually reduced, maintaining the patient on the same diet or insulin might be stopped for several days and the patient's sugar tolerance can then be recognized and the dose of insulin either reduced or entirely stopped. It has been my experience that in the milder cases patients who are overweight, when placed on a basal maintenance diet, usually respond promptly without any necessity for the use of insulin.

6. If the patient is admitted to the hospital in a state of acidosis, he receives preliminary carbohydrate, low protein and no fat diet with insulin until he is freed from this complication, when he is treated in the routine way as detailed above. If the patient reaches the hospital with impending coma or in coma, insulin in a large dose (thirty or forty units) is at once administered and doses repeated until the blood sugar falls within normal range and the alkali reserve is restored, and other routine measures including alkali, stimulation such as digalin and adrenal, stomach lavage, lumbar puncture, etc., are given. After recovery from this complication he then receives treatment as outlined for other diabetics.

7. If a patient has an intercurrent disease like tuberculosis, or pneumonia, or nephritis, it is best to use larger doses of insulin and a more liberal diet in order to sustain the patient during this emergency or as, for example, in tuberculosis, where nutrition and gain in weight are important factors in controlling the intercurrent disease.

8. Patient's weight is recorded at three or five day intervals to ascertain how much gain occurs on basal diets, and upon leaving the hospital, it is wiser to slightly increase the dietary allowance (say twenty per cent.) in proportion to insulin doses allowing for the patient's increased activity. This will prevent the possibility of untoward reaction from insulin, and if the patient excretes a trace of sugar and runs a high normal blood sugar in consequence, it will do him no harm. The patient is also instructed to carry with him candy or sugar at all times so that he may promptly administer the antidote if an untoward reaction occurs.

INSULIN IN CHILDREN

Children above ten years of age receive the same routine as adults. In younger children it is harder to estimate basal maintenance diet or caloric requirements, since children are active. Young children require at least one half the food allowance of adults with relatively larger proportions of protein and sugar. Because of their low blood volume, smaller doses of insulin are necessary than for adults. Children have a greater tendency to acidosis and, because of the small blood volume, sometimes the blood sugar drops abruptly after insulin injection and they therefore require more careful watching.

In general the rule applying to adults, namely, beginning small doses at first and gradually feeling one's way with insulin diet balance, should be more rigidly emphasized in children. Lastly, insulin promises to be of value in other conditions; notably, as

pointed out by Thalheimer, in apparently nondiabetic acidosis. It is encountered in children and postoperatively frequently. Here sugar administration intravenously, plus insulin, brings about cessation of vomiting, avoiding exhaustion and undernutrition. In the hospital we have also used it with encouraging results in cases of undernutrition due to various nondiabetic causes as, for example, the vomiting associated with brain tumor and stomach carcinoma.

After all, the treatment of diabetes must continue in the hands of the general practitioner because we have more diabetics today than ever and because, with the improved methods of treatment diabetics live longer. From my experience in outpatient and private diabetic treatment, I can absolutely refute the assertion that it is necessary for a patient to be hospitalized in order that insulin and dietary measures be carried out successfully. In outpatient and private practice we estimate tolerance for carbohydrate by placing the patient on a given diet and estimating how much sugar is then thrown out into the urine on that diet. By either subtracting that quantity of sugar from the diet of a patient who is overweight, or adding insulin to the regimen to take care of this excess sugar in individuals below weight, excellent results are obtained.

Patients have their urine examined either once a week or once in two weeks and the blood sugar estimated once in every two weeks to determine increased tolerance, and they are also weighed as regularly to maintain weight levels. This routine can be followed out in the office of the general practitioner with ease.

1204 Spruce Street.

Alcoholic Nerve Block for Pain in Malignant Diseases*

GEORGE I. SWETLOW, M.D.
and BERTHOLD WEINGARTEN, M.D.
Brooklyn

The control of pain in malignant diseases has always been one of great concern to the attending physician. The incessant employment of morphine in the care of these patients has serious disadvantages which may be summed up as follows:

1. Small doses of morphine afford little relief.
2. The perpetual use of morphine quickly raises the tolerance to the drug. As a result even large doses often fail to ameliorate the pain.
3. Morphine even in small doses may actually hasten death in the extremely weak and debilitated patients.
4. The drug so dulls the intellect that both the family and the patient are denied even the companionship of the last days.
5. Opiates are especially dangerous in diseases of the lungs for they greatly reduce the cough reflex. As a result the secretions are often brought as far as the bifurcation of the bronchi and are dropped back into an unaffected area. Thus a terminal pneumonia is produced.

The cases here reported have been treated by alcoholic injections into the nerve supplying the diseased area.

Case I.—H. P., male, aged twenty-six. This patient had a neoplasm of the lung, the diagnosis being established both by physical and x ray examination. The pain, which began September, 1924, was localized in the left axilla. He described it as being burning and boring in character. The slightest movement aggravated the distress. Even a light touch to the skin produced unbearable anguish. The pain had been present constantly both day and night, with no relief until the date of our treatment. Five months after the onset he complained of pain in a new area in the region of the lower part of the left scapula. He described it as stabbing and sticking in nature, and as a result found it impossible to raise the left upper extremity. Any movement whatsoever greatly aggravated the distress. He found it practically impossible to rest on his left side. This pain had persisted for a period of four months before treatment was instituted. Physical examination showed two dermatomic areas of marked hyperalgesia on the left side. One area involved the skin segments supplied by the second to the fifth dorsal spinal nerves. Another area extended from the seventh to the eleventh spinal nerves. Slight pressure over the intercostal spaces supplied by these irritable nerves produced unbearable agony. Even the application of a stethoscope to the chest wall was intolerable. Three cubic centimetres of a sixty per cent. alcohol solution were introduced paravertebrally into the intercostal nerves supplying the hyperalgesic skin areas. The accompanying diagram shows the intercostal nerves injected (Fig. 1). The patient's condition after the injection may be summarized as follows: The hyperalgesia in the affected zones became markedly lessened. The unbearable pain induced on pressure over the intercostal spaces was greatly diminished. The application of a stethoscope to the chest wall elicited no discomfort. For the first

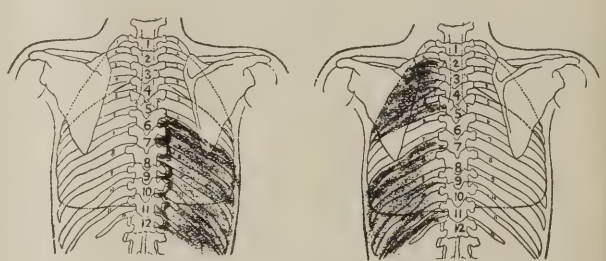

Fig. 1.—Case I. Showing the intercostal nerves injected.

*From the Cancer Division of the Montefiore Hospital, New York City, Dr. G. Gottesman, Surgeon-in-charge.

time in months he was able to sleep on the affected side. He was relieved until the day of his death, a period of thirty-three days.

Case II.—R. R., female, aged forty-eight. This was a case of carcinoma of the breast with very severe pain produced by pleuritic involvement. In another article a preliminary report was made in which five cases of severe pleuritic pain in pulmonary tuberculosis were treated with paravertebral injection of alcohol. This patient was treated similarly.

The treatment of this patient was based on the following anatomical and physiological facts. The upper six intercostal nerves supply the upper parietal costal pleura. The lower six send their intercostal fibres to the lower parietal costal pleura as well as the parietal pleura of the diaphragm. Disease, therefore, in the costal parietal pleura will convey its effects in the form of pain to the chest wall. The site of reference will depend upon the intercostal nerve impinged. With the blocking of the nerves supplying the diseased pleura, pain stimuli would be prevented from reaching the sensorium.

Fourteen years before admission the patient had a mastectomy done on the right side for malignancy of the breast. Several months later a severe, sharp, stinging pain developed in the lower right chest. This pain persisted on and off for several years. Three years ago there was another exacerbation of pain. Eight months ago the pain became intolerable. It was sharp and sticking in character, and with the sticking pain there was present a burning sensation. The pain was localized in the posterior and anterior lower chest and down the loin and abdomen on the right side. She then first noted a boring pain over the upper dorsal spine which gradually increased in severity and had become so severe that she could not recline on her back. Mere palpation of the four lower ribs anteriorly induced intense pain. The vertebræ showed no x ray evidence of metastases. The right chest was aspirated and seven hundred and fifty cubic centimetres of a clear fluid were removed. Tumor cells were found in this fluid. Physical examination showed a level of hyperalgesia extending from the sixth to the twelfth dorsal segments. A paravertebral injection was performed. Each root was injected with three cubic centimetres of an eighty per cent. solution of alcohol. Immediately following the preliminary injection of a one per cent. novocaine solution, the pain disappeared. Pressure and fist percussion elicited little pain. Following the injection with alcohol she has been relieved to the present date, a total of fifty-eight days. She is now able to lie on her back. Movement elicits no pain. Heavy palpation or fist percussion elicits little discomfort.

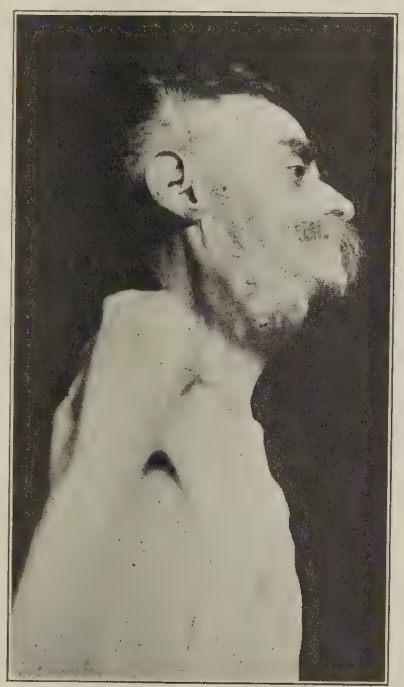

Fig. 2.—Patient in Case III.

Case III.—A. S., male, aged fifty-eight. This was a case of carcinoma of the tongue with metastases and extensions to the floor of the mouth and the neck. The following anatomical and physiological facts were the basis upon which this patient was treated. The inferior maxillary nerve, a branch of the trigeminal, has both sensory and motor components. The sensory fibres arise from the lower anterior portion of the Gasserian ganglion and supply the skin over the side of the head, the auricle of the ear, part of the external auditory canal, the lower portion of the face and lip, the mucous membrane of the mouth, the tongue, the lower teeth and gums, salivary glands and the temporomandibular articulation. The mandibular nerve enters greatly into the supply of the salivary glands. The parotid gland is supplied in part by the sensory fibres of the mandibular nerve through the auriculotemporal branch. The submaxillary and sublingual glands are supplied to a great extent by the lingual nerve, the large branch of the mandibular nerve.

At the onset, the patient complained of severe neuralgic pains in the right occipital and temporal regions. He was seen by the dentist, who removed all the teeth on the right side of his mouth, both upper and lower. The dentist told him that he had "proud flesh" under the tongue. One month later two white spots appeared at the root of his tongue, which were soft and which did not bleed readily. These were cauterized but reappeared the next month and were pin point in size. Eight months after the onset, the patient noticed an enlargement on the right side, involving the lower jaw and neck. This swelling became progressively larger and was accompanied by a severe burning pain in his throat. X ray treatment afforded him no relief. The pain had become so intense as to necessitate the use of large doses of opiates and so severe as to force him to limit his diet to fluids. The diagnosis made was carcinoma of the tongue with metastases and extensions to the neck. Physical examination showed the following: The tongue deviated to the right and great difficulty was experienced in protruding it. There was a large mass on the superior and posterior aspect of the tongue. In the right submaxillary region there was found a large, nontender, nonremovable mass, extending anteriorly beyond the midline and posteriorly behind the sternocleidomastoid muscle. His mouth was constantly filled with saliva and he drooled incessantly.

Following the injection of the right inferior maxillary nerve with five cubic centimetres of a sixty per cent. alcohol solution, great relief from his symptoms was obtained. His pain became markedly less so that the amount of morphine required could be materially cut. His sputum became materially lessened and more viscid in character. He was relieved for a period of fourteen days before he died.

A Psychoanalytic Introduction to a Study of the Conduct Disorders of Lethargic Encephalitis*

With Outline of Plan for Psychosocial Reconstruction

L. PIERCE CLARK, M.D.

New York

(*Concluded from page* 647)

At this point the child said she was going to try to do what was right to get well. The meaning of many of the coarse words she used was explained, and this also seemed to be a help for she had no idea of their real import. She slowly developed insight and spoke somewhat pathetically: "I didn't get along well with the children today, they made me mad and I called them names, but I did not get as mad as I used to; I am getting better, ain't I? I am trying to do what you tell me." On one occasion following a mild protest against ordinary routine directions she looked rather hatefully at her instructor and declared that she would do as she pleased. She then began to cry and said, "You don't seem to understand me—I don't mean to be this way—I don't mean to do these things. I love you and I hate you—how can that be? Was there ever such a thing?" The child gained considerable control over her impulsive acts and seemed capable of putting into operation the insight she had gained from her general training. These periods of insight gradually extended and deepened under the pacific guidance and comprehending attitude of those in charge.

Psychoanalytic reeducation, but not psychoanalysis, was undertaken in this case, but it is hoped that psychoanalytic procedure will be available to other cases of this type in future, in order to gain a better understanding on the part of the patient of the emotional levels to which he has regressed under the onslaught of this destructive disease. The case is given as an example of what may be accomplished when a wise and gentle training is instituted and a conscious insight gained although the patient may remain unaware of the conflicts which precipitated the conduct reactions. The details of the case management are not unique but may perhaps be called the better sort of reeducation plan of treatment for such children.

Our next case is an example of the psychoanalytical approach to this problem.

CASE II.—H. P., a nineteen year old boy, well developed, fine featured, with an intelligence quotient of 106, was referred to me by the social service department of one of the large city hospitals as an unadjusted problem. The medical findings carried over a four year period can be briefly summarized: A diagnosis of lethargic encephalitis was made in 1921. At the onset of his attack of encephalitis, after a day of hard work on going to bed he noticed that he had double vision. He was enjoined to be quiet and recline in a darkened room. For three or four days and nights he remained wide awake, after which a sleep succeeded attended by a delirious coma with almost constant repetition of the words, "needles and pins." A period of nine weeks of almost unbroken sleep left no doubt of the accuracy of the diagnosis. The clinical history shows that this sickness was followed two years later by a complete character change. Physical symptoms, developed at a more recent period, are characterized by a constant coarse tremor of the left hand, sagging of the jaw, and Parkinsonian mask. The boy was returned to school after a loss of one term. Sympathetic treatment gradually built up a feeling of invalidism and evasion of duty. The sleeping spells have gradually decreased and have been replaced by loss of memory. The boy is markedly temperamental, gloomy, sensitive, impulsive and suggestible.

The successful beginning made with this patient by psychoanalysis was in a large measure due to the confidence of his family in the personnel of the institute from which he was referred, the intelligent cooperation of his mother and the narcisistic transference he was able to make to the psychoanalyst and his assistant. From the first interview the boy kept his appointments willingly and promptly and seemed not disheartened by the clear understanding that the treatment might lead only to a better general understanding of the disorder and not to personal improvement. It is interesting to note that until this case come for analysis it had been most difficult to gain the cooperation of these patients or their families; during the years they had suffered from the sequelæ of this disease, the patients had been subject to such an unending round of medical, institutional and social care that hope had failed and further therapy held little appeal.

At the time of this report, the boy had had but three weeks analysis. Inasmuch as a narcisistic transference only was possible, the phantasy method (2) was employed to reinvoke the earlier oral and anal mechanisms at their weaning periods. It was not until the phantasy method was used that the descriptive phase relating to his scholastic and musical ambitions was put aside and the infantile attitude laid bare with its surcharge of emotion. The patient's whole manner changed to a childish simplicity of tone and feeling. He again relived the period of being rocked in his mother's arms and nursing with a savage eagerness that made his body glow with warmth and exhilaration. In one analysis the patient said, "I was a delicate child. My mother would wrap me in a warm blanket and hold me close to her breast. It seems as if it were yesterday. Oh, it was just like heaven. I would pull her breast as if I wanted to suck the life blood out of her. Sometimes I would bite her nipple; it makes me feel very sad to think that I made her suffer so, yet I could not always repress the desire. Oh God, what terrible days!" One may infer from this and more extended

*Read before New York Neurological Society, February 2, 1926.

data the usual source of sadistic desires. Then came the weaning trauma and the bottle that was left with the child during the day when the mother was away. "Mother's breast was the first food I knew. I loved it so. When the time came to give it up I couldn't get used to it, I felt as if mother was going away, too, as if she didn't love me. The bottle seemed like an impostor, as if it were taking the place of mother and had no right to. When mother was away I'd hug the bottle close to me in both arms and suck the milk from it. When I had the bottle next to me, I could take milk whenever I wanted to. I had it by me all day, but it wasn't satisfying. I missed the touch of mother's breast. When it came to other food, mother would feed me; I liked it better than the bottle—she was there. She would take a spoonful of oatmeal and take it up to her lips and blow upon it—meanwhile telling me a story; that made it easier to eat. The food tasted nice as long as mother was telling a story, but when she stopped, sometimes I'd begin to cry. When she was close to me I always felt her warmth going through me—always—even now. When there was no mother, no bottle, no food —my mother would leave me on the floor and I'd build castles out of my blocks." At the close of each analytic session when the patient had retreated to these blissful states of nursing, he would fall into a profound stupor from which he was roused with difficulty. He would mumble, "Yes, yes, I hear, but can't you leave me alone for awhile. The world is so very sweet!" One gains an idea of the acute demoralization engendered at the weaning trauma, the intensive mother attachment and the difficulty of releasing himself from her in the following: "It made me feel all warm when she came into the room —her face was loving—just like an angel's. I was always lonely—I would sit on the floor and play with my blocks and little steam engine, but when she came in I wasn't lonely any more—just happy and contented—her face looked like the Virgin Mary's, and her smile and her eyes were warm and glowing. When we were in bed, she would hold me close and I would put my hand on her neck—it felt all creamy soft and I liked to touch it." When the phantasy is continued again, the patient exclaims, "Please, I don't want to go back to those little boy days, they are too painful, they prove the realization of all my mistakes and all that I wanted to be—I sat and played with blocks on the floor, all day long when mother was away. I used to build beautiful houses and imagine that my mother and I lived there in a Utopia, the kind of a land where one never has any harm befall one. I used to build houses when I grew older, and my wife lived in them, too, but always my mother. I think that is the trouble with me, I am too milkfed, too carefully protected. Perhaps if mother had let me play with boys and think boy's thoughts I would not be the kind of person I am today."

One may here note his insistent demand projected upon the mother as her fault in not letting him be a boy, etc., and still later we see the early formation of the mother as a loved object (Œdipus). The patient states:

"I first remember father sitting in a rocking chair —mother was sitting on father's lap and she was crying, he had no job. My uncle took us in—she was very sad. The baby looks up in mother's face as if to say. 'Don't cry.' Sometimes I felt angry at my father, wanted to put all the blame on him, but I afterwards realized he was trying his best. I felt angry—my mother was such a beautiful lady and so good—my father ought to try more than his best to support her and praise her. I'd pay no attention to father. I'd just walk over to mother and take her arm and caress her. She would pick me up and hug me and cry convulsively and I'd feel sorry for her. I'd sometimes feel like killing father. I remember saying to mother when father was sleeping that we should throw him out of the window and the undertaker would come and take him away."

Finally the rapid regression from fairly well controlled (psychically mastered) states to the deepest sadistic attitudes is shown in the following analytical material: "When I was five years old I was very angry at my mother because she had promised to be at the concert—then she disappointed me at the last minute. I got all heated up; the blood came to my temples; I felt like leaving the stage, but when I saw my mother everything was all right. When I am improvising music, my mother doesn't like it and stops my playing—she doesn't like it and I like it; I feel infuriated. If I surrender to the impulse I'd kill her, but I calm down right away and consider her feelings. I get all hot in a minute and walk up and down the room and have to go out in the fresh air and do something to give vent to my energy. I'm afraid some day I will kill somebody. The impulse comes when anyone arouses me. When people contradict me, when I'm sure about something; I hate to have anyone contradict me. I believe a man isn't a man unless he has a spark of jealousy in him. I went to a party recently and my best friend whom I trust implicitly took my girl friend home. I would have killed him on the spot and he is my best friend, too. The only satisfaction I would get out of choking a person would be a very bloody satisfaction. That boy in the country who teased me and made me mad—his tongue was hanging out and his face was all red—almost purple—they dragged me away from him. I have no revolver and don't keep a dagger about me, so the only way I can think of killing a person is by choking him. I hate to think about it even for a second. All my hot blood is thrilled and then the next minute I am sorry. Believe me, I never meant it (deep sigh)."

Only one session was given to the patient's love for music, which, however, gave ample indication of the possibility of sublimating a deep seated urinary eroticism into rich aesthetic expression. Only by reading the text of the original material can an idea be gained of the child's pleasure in urination. Then we find the baby "laughed and crowed with glee as the urine fell into the basin with a tinkling sound." The baby loved the noise so well that he would hold it in as long as he could so it would rush forth as loud as possible. This field of early infancy may be of great interest in the revelation it might hold of how the rhythm, pitch and rippling flow of urination might be the beginning of a delight in the myriad sound possibilities of the sensitive violin. The sadistic impulses that had played so devastating a rôle in the sequelæ of this patient's illness were pictured in a colorless tone. The boy was apparently quite unconcerned with the outbursts of uncontrolled, unrea-

soning and violent tempers. Sufficient time has not yet been available to drive the interviews down to an anal erotic level, or to discover what insight the patient might have gained during the brief period of analysis. The time has been so fully occupied in the production of new material that no attempt has yet been made to have him apply his own data for a possible modification of character; nevertheless it is evident that many of the old emotional fixations are being drained and that a therapeutic process is under way. At times there is a marked change in the masklike rigidity of the boy's expression, and the mother's statement bore further proof of changing attitudes: "He no longer spends his time quarreling with the family or sitting like a stone image talking about making away with himself. He reads books and papers now, wants a new suit of clothes and says if he can only get a job he is sure he can do something to help himself get well." The mother further states that the physical symptoms have much improved since their first acute onset and that she believes the boy will keep steadily on the mend if his interest in life can be sustained.

The boy in turn feels that much is lacking in his own adjustment and is gradually gaining insight. "I love music, but sometimes I wish I had never heard of it—all the time when I was little I kept at practice, practice. It would have been better for me if I had been allowed to run free and do the things the other boys did."

The results of these analytic sessions are by no means final, as insufficient time has elapsed to show what effect psychoanalysis might have in one suffering from a degenerative brain lesion. However, it is just possible that through the transference and new interests the symptoms may disappear for a time and give us an opportunity to build up the psyche to keep abreast of the degenerative process.

PLAN

I shall state briefly my proposition for psychosocial reconstruction of these conduct disorders following lethargic encephalitis. A well ordered home in the country should be established for a limited number of suitably selected cases. Here the proper reëducational program of care, occupational training and instruction in social behavior should be instituted. A psychoanalytic study of this acute ego neurosis should be carried out which will determine the degree and extent of trauma sustained by the ego organ of the psyche, which when determined shall be the real guide to all other systems of care and reconstruction. The total estimated cost for such experimental therapy for handling four or five resident patients under intensive analytical study and training would be between $1600. and $1800. a month. This would provide for rental of a comfortable house in the country with ample space for outdoor occupations, a middleaged couple in charge to provide the proper home background, two trainers of the companion type, a cook, houseworker, laundress and miscellaneous expenses for providing good food and good living conditions. This also includes the cost for daily analysis by trained analysts and an assistant to record the data for study.

In the absence at the present time of such a place for the study and treatment of these cases as outlined and submitted to the National Committee of Mental Hygiene and the ideal plan just outlined, undoubtedly many encephalitics under a State hospital regime could be analyzed and by the use of the parole system a modified application of normal activities could be employed as necessary and desirable. It would thus be possible to see whether a recurrence of the social maladjustments in these postencephalitic patients could be permanently removed, thus permitting normal living in the community. I may add that such an investigation of this problem upon specially selected cases is being carried out at the Manhattan State Hospital.

In conclusion we may state that in the encephalitic process a pathoneurosis is entailed in consequence of the imprisoned narcisism which fails to heal or remove the lesion and thus overflows into the whole behavior reactions of the youthful patients, making the clinical picture so pathetically classic and antisocial. While this study is no more than a preliminary communication, nevertheless our psychoanalytic investigation so far undertaken gives us reason to believe that our hypothesis is not only correct in principle but also lends much to the indication that our method of bringing about an amelioration of the state is a workable one. We admit that we are proposing a plan of analytic treatment to cover the most incorrigible and intangible types of cases from which all grades and kinds of conduct disorders shade out into those of the more or less pure transference type. In the latter, of course, the analytic task may be comparatively simple, and no more than a wise psychoanalytic reëducation may be necessary. Only time and a larger case study will prove the correctness of these conclusions. Undoubtedly the reappearance of conduct disorders when these patients supposedly recovered from their antisocial behavior are returned to the home environment, is due to the incomplete analysis of the parental identifications and the nonabsorption of these patterns of identifications into the ego. The latter is due largely not to an insufficiency of the controlling energy of the ego nucleus but to the extreme narcisism that prevents sufficient projection and adhesion of object libido to seize upon interests in the outer world, to retain it and permanently incorporate it into the total ego formation. Therefore the amount of transference and the vividness of object appeal holds the key to our therapeutic endeavor. To the means of intensifying the latter we must now address our main attention.

Finally, one may tentatively postulate upon our clinical and theoretic data that the conduct disorder of postencephalitis lethargica is an ego (narcisistic) neurosis which may be studied not only objectively and managed more understandingly than in the past, but that it is not inaccessible to psychoanalytic investigation; and to the efforts of the neurologist may be added those of the psychoanalyst, both enlarging our knowledge of organic psychiatry by mutually helpful cooperation in their respective fields.

The Problem of the Macerated Fetus

MEYER ROSENSOHN, M.D.
New York

In spite of the increasing success attendant on the efforts of modern preventive medicine it is astonishing to note the record of the stillbirth rate. A gross rate of forty-one per one thousand as we have had at the New York Lying-In Hospital in 1924 is discouraging; nor is it any the less so to compare it favorably with a general stillbirth rate of forty-seven per one thousand for New York as a whole, or with the rate of fifty-three per one thousand for Detroit.

As an explanation of these high figures, in a measure, it is important to keep in mind the application of the term stillbirth. In this city, if a recognizable embryo is passed with the products of gestation or if a fetus be born with no respiratory effort, though its heart may be beating, a stillbirth certificate is required. In this way, an embryo of three months, or what ordinarily would be called an abortion is a stillbirth; again, a premature or a full term fetus comes under exactly the same classification. It becomes apparent then, that the mere enumeration of figures for this type has little significance, nor can it be used as a basis for comparison. Yet of all the classes of stillbirths, the greatest numerically is represented by the socalled macerated fetus. For the most part, even before labor is initiated, a good proportion of the stillbirths have ceased to live and already begun to undergo decomposition. The following table shows this strikingly for the year's work at the Lying-In Hospital (1924):

Total confinements, 5,457.

Total stillbirths 227 or 4.1 per cent.=41 per 1,000.

Total full term macerated, 94 or 1.7 per cent.= 41 per cent. of stillbirths.

Stated in another way, these figures mean that almost half of our stillbirths were probably dead before admission to the hospital. No method of treatment, no interference at this time obviously can be successful in reducing the fetal mortality. Distinctly then, in the field of preventive medicine, of pre-natal care, it is of the utmost significance to inquire into causes so far as ascertainable. Almost at once, one is struck by the discrepancy between our figures and those frequently referred to. Syphilis is by no means a common cause, this is borne out, both by the records of 1924, and also, by those of the nine months of 1925 to October 1st. The figures are almost exactly the same from this point of view, as will be seen by the following tables:

Year 1924

Macerated fetus	94
Positive Wassermann in mother	15
Negative Wassermann in mother	60
No Wassermann taken	19

	January 1, 1924, to October 1, 1924	*January 1, 1925, to October 1, 1925*
Macerated fetus	72	71
Positive Wassermann	10	8
Negative Wassermann	44	55
No Wassermann taken	18	8

Noted differently, in more than half of the cases of macerated fetus, there was no evidence of syphilis, clinically, by test or by autopsy.

Looking further into the causes the striking figure is represented by the cases occurring in toxaemic mothers; there were thirteen of these, fourteen per cent. of the stillbirths. The following table gives the causes which were ascertained:

Toxemia and eclampsia	13
Previous stillbirths	5
Diabetes	4
Tight cord	3
Fall or blow	2
Placenta previa	2
Hydrocephalic monster	2
Pyelitis	1
Premature separation placenta	1
Fibroid uterus	1
General peritonitis in mother	1
No ascertainable cause	44

In the figures quoted in these tables we have some indications for preventive measures. We have every reason to expect results, from specific treatment, started early and pushed assiduously in the luetic cases. Close observation from the earliest recognizable period of gestation with proper regulation of diet, hygiene, etc., can expect to reduce considerable the number of toxaemic and eclamptic cases. The diabetic, by proper dietary regulations and medical treatment may also be carried through a normal confinement. A few of the causes listed in the last table may, by appropriate treatment, be eliminated.

But the most disappointing feature at the present time is the number of cases in which the cause is unascertainable or unrecognizable. In forty-four cases or almost half our full term macerated fetuses, we could not discover any cause for the intrauterine death. How to attack this group is a most worthy problem. Its solution, it seems to me, depends on an intensive, cooperative effort between internist and obstetrician; a study, more thorough than ordinarily can be accomplished in the antepartum clinic, and should be undertaken by a skilled medical man to determine the existence of focal infection. The newer developments and tests for the determination of function of the various organs, including especially the internal glands, should be applied, the bacteriological study of the vaginal flora may reveal significant factors. It is only by such methods, that we can hope to prevent intrauterine deaths which occur in such a large portion of our stillbirths.

SUMMARY

1. The stillbirth rate at the New York Lying-In Hospital for 1924 was forty-one per one thousand.
2. The macerated fetus represented almost half of the stillbirths.
3. In the cases of macerated fetus, syphilis was present only in fifteen of the ninety-four cases.
4. Toxemia and eclampsia accounted for thirteen.
5. In forty-four no cause could be ascertained.
6. There should be a thorough examination made in every case of pregnancy by an internist, as well as by an obstetrician, and the mother closely watched throughout.

An Approach to the Study of Pyorrhea Alveolaris*

ALFRED J. ASGIS, ScB., D.D.S.
New York

(*Concluded from page* 688)

In the United States only recently has emphasis been laid on the fact that it is not the brushing of the teeth that is aimed at which is to prevent pyorrhea, but that it is gum massage that must be stressed as a measure in increasing the local tone and resistance of the peridental tissues (38), (39).

Aside from the inadequacy of the value of the tooth brush, whether in the prevention of pyorrhea or decay, attention was called by Withhaus, of The Hague, that in his long experience he found that there must be some etiological relation between the brushing of the teeth and the breaking out of what he calls "the pernicious pyorrhea alveolaris" (45). Polet (46) of Brussels calls attention to the frequency of gum infection through the vigorous use of the tooth brush causing a chronic gingivitis, termed by him "chronic pseudo Vincent."

Attention (48, 49) was called to this inadequacy of mouth hygiene as practised today in an editorial in the New Haven Department of Health *Bulletin*. The advisability of the use of the tooth brush for purposes of gum massage, either for general mouth hygiene or for the prevention of pyorrhea, is questionable, although it is suggested that to derive the full benefit of the tooth brush in gum massage it should be used for fifteen minutes each time when used.

Considering the fact that many constitutional disturbances, such as chronic diabetes, nephritis, intestinal intoxication and an array of others are associated with pyorrhea in causal relationship and that focal infection, on the other hand, may be responsible for systemic disease as well as for metabolic disturbances, it is difficult to determine as to what extent infection, either of the focal or local type, is responsible in the inauguration of pyorrhea alveolaris. From the viewpoint of focal infection, the presence of the focus as a factor in inaugurating systemic disease is of primary importance, whether this focus be located in the jaw bone, the tonsils or in the intestinal tract.

We may, therefore, consider oral focal infection as a condition of disease in the jaw bone, contributory to alveolar atrophy. Much of the confusion in speaking of the different theories advanced by the localists has arisen from the fact that it was assumed that all localists considered the disease as from a local standpoint only, therefore local treatment was indicated. From the viewpoint of prevention, however, local treatments, such as are in vogue today, must be considered as to what extent these measures in themselves are contributory to the causation of pyorrhea alveolaris. When we take this attitude we find that the study of the etiology and treatment of this disease like that of any other disease that the human flesh is heir to lies in the domain of medicine and as such needs to be approached from a medical, biological point of view. This would imply the elimination of focal infection, the regulation of the proper dietary and the establishment and maintenance of mouth hygiene as a preliminary requirement in the study and treatment of pyorrhea alveolaris.

*Read before the Eastern Dental Society of Philadelphia, Pa., on December 3, 1925. Contribution to the Annual Symposium on Stomatology of the American Stomatological Association.

Instruments, Apparatus, and Clinical Notes

High Enemata and Irrigations

MARKS S. SHAINE, M.D.
New York

Chronic constipation is a progressive disease. It operates in a vicious circle. Constipation begets constipation. To break the vicious circle it is necessary to keep the bowels thoroughly evacuated for a time until the remedial measures that are contemplated have had a chance to accomplish their purpose. The evacuation of the bowels can be brought about either by the use of cathartics or by enemata and irrigations. The objections to the use of cathartics in chronic constipation are too well known to need enumeration and comment. It is with the details of the administration of enemata and irrigations that this paper is concerned.

Beside chronic constipation there are other conditions which are often treated by enemata and colonic irrigations, e. g., intestinal toxemia, or socalled auto-intoxication, colonic stasis, migraine, hypertension, arthritis, etc. Without committing myself as to the utility or futility of colonic irrigations in these affections, I merely want to describe a method of colonic irrigation which in certain types of cases I believe to be superior to the methods now in vogue.

Chronic constipation is now generally considered to be in the great majority of cases a spastic phenomenon. The spasm exists most often in the lower sigmoid; less often in the external or internal sphincters, and more rarely in the descending, the transverse colon or in the cecocolonic juncture. Mueller of Vienna believes that all constipation is spastic in origin and that there is no such thing as atonic constipation.

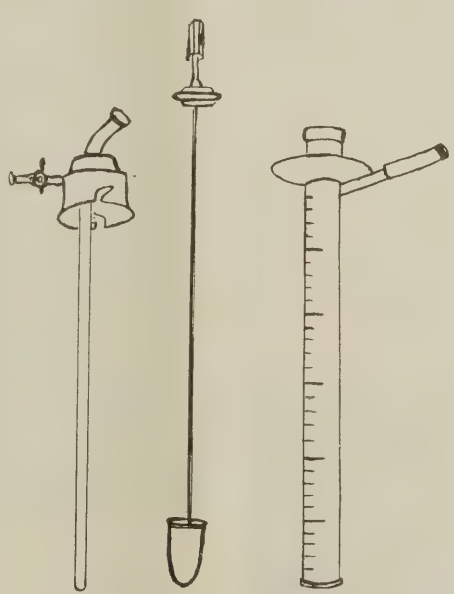

Fig. 1.—Instrument used for high colonic irrigations.

Spasm in the lower sigmoid is by far the most common condition and accounts for most cases of constipation. X ray examination of the patients in this group, forty-eight hours after a barium meal, shows most of the barium collected in the lower sigmoid. On sigmoidoscopic examination one finds the rectum empty of feces, but the further passage of the instrument becomes impossible on account of the solid mass of feces which it encounters.

In this type of constipation the patient's reaction to an ordinary enema is often quite characteristic. Either the water will not flow in at all or, if it does, will cause severe cramps because, being unable to pass into the sigmoid, it distends the rectum to the point of pain. If it does pass beyond the constricted point under the pressure of the water used for the enema, it remains in the higher colon, because there is not enough *vis a tergo* in the colon to expel it past the spastic portion of the sigmoid. This accounts for the patient's complaint that enemata are not only painful but useless, as the water injected either fails to return or else returns clear.

By fluoroscopic examination it can be demonstrated that in the majority of cases an opaque enema given with the ordinary fountain syringe will reach the cecum if a sufficient amount of fluid is injected. But in patients with spastic constipation, enough fluid cannot be injected to fill more than the rectum and a small part of the sigmoid, on account of the pain which the injection causes or the patient's inability to retain it. If a large part of the colon should be filled, and the patient then asked to evacuate his bowels, fluoroscopic examination will show most of the opaque mixture retained in the colon.

To overcome these shortcomings of the ordinary enema, high enemata and high irrigations are frequently employed. But by fluoroscopic examination it has been demonstrated that a rectal tube, even a rather stiff one, when inserted full length into the rectum curls up on itself and does not pass further than the ampulla of the rectum. Fig. 2 illustrates what occurs when the ordinary rectal tube is introduced full length into the rectum. Fig. 3 is a film taken when a rectal tube was inserted just beyond the internal sphincter and water allowed to run through the tube which was then inserted full length, with the expectation that as the water distended the bowel the tube would more readily pass high up without curling on itself. That this is not the fact is proved by this film.

A sigmoidoscope was introduced thirty c.m. then a long rectal tube was passed through it and the instrument withdrawn, while the tube was held firmly and prevented from coming out with the instrument. Fig. 4 shows the tube reaching high into the colon. If the tube be now connected with a fountain syringe a high enema can be given and allowed to return through the tube. A wide firm tube with an opening at the end is best for this purpose.

In administering an enema in this way, a larger amount of water can be injected without causing pain. The enema is allowed to return through the tube and the larger fecal masses, which would be detained at the narrow spastic portions of the sigmoid, readily pass out through the tube.

For high colonic irrigations I use the instrument shown in Fig. 1, which was made for me by Mr. R. Wappler, of the Wappler Electric Company. It is constructed to fit the Lynch sigmoidoscope. It is simply an application of the principle of the Kemp tube, or of any double flow irrigator, to the sigmoidoscope. The illustration needs little explanation. The afferent tube is connected with a two or three gallon irrigator by tubing, in the midst of which is interposed a bulb with a stopper so that if fecal matter clogs the tube it can readily be expelled. The efferent tube is connected with the drain pipe of a water basin, so that no fecal odor escapes into the room. This tubing, too, has interposed in it a larger bulb so that suction can be made if the tube be clogged with feces. A Lynch sigmoidoscope is inserted full length, the light carrier removed and the irrigator is attached and the fluid allowed to run. Two gallons can be used in fifteen minutes.

Fig. 2.—Showing what occurs when the ordinary rectal tube is introduced into the rectum.

Fig. 3.—Showing rectal tube inserted just beyond the internal sphincter.

In many cases, where the symptoms were pain, colic and constipation, which were not relieved by medication or by ordinary enemata, definite improvement followed treatment by high irrigations with the method described above. One typical case may be briefly cited.

Case.—A man, sixty years of age, had been suffering for a long time from a severe spastic constipation. Cathartics of any kind caused severe cramps. Milder laxatives and mineral oil were wholly ineffectual. An enema or two enemata in succession were not effectual; they produced very little stool, caused severe pain, and he had great difficulty in expelling the water. He had had frequent attacks of severe abdominal cramps which at first were diagnosed by two able physicians as acute appendicitis, but afterwards it was evident that they were nothing but severe spastic constipation. I stopped all cathartics and for three months gave him irrigations, as described above, at first twice weekly, later once a week. He was practically free from pain all that time.

Fig. 4.—Showing the tube reaching high into the colon.

I believe that the effectiveness of the Murphy drip would be much enhanced if it were given through a tube inserted high up into the descending colon instead of through a tube opening into the rectum. It would be well to introduce the tube in all laparotomy patients before operation and allow it to remain there for the first three or four days. It would aid in the expulsion of gas and be useful for the Murphy drip, for nutrient enemata, for medication, for high enemata, etc. While the rectum can absorb only water, glucose or peptones, it is possible that the higher colon can absorb other nutritive materials. There is no doubt that larger quantities of fluid can be more quickly absorbed from the higher colon than from the rectum.

The introduction of a tube high in the colon undoubtedly will diminish flatulence and abdominal distention which, in some cases at least, may be due to a spasm in the lower (sigmoid) colon. By keeping

this part of the colon continually open this most annoying complication may often be avoided.

CONCLUSIONS

1. The high enema as usually given is not a high enema, and is no more effectual, perhaps even less so, than the ordinary enema.

2. A method of giving enemata and high irrigations is described.

3. The introduction of a tube into the upper sigmoid or descending colon in patients before laparotomy is recommended.

The Cystoscope as an Aid to Diagnosis*

JOSEPH SCHWARTZ, M.D.

New York

To many cystoscopy seems a needless procedure, giving great discomfort to the patient and being unnecessary in the search for pathological lesions which our clinical sense may be able to discover without it. From the numerous instances where cystoscopy was indicated I was much impressed with its accuracy as a diagnostic measure and the absence of discomfort or serious aftereffects. The cystoscope has been heretofore regarded as an instrument of the genitourinary surgeon, but nevertheless the general surgeon and the gynecologist should become familiar with its use, as it deserves a thorough consideration in its broad field of utility.

In this paper I do not intend to make an exhaustive study of the cystoscope and its various applications, but only to mention some conditions as they occurred among our cases where the cystoscope and its associated procedures, such as ureteral catheterization and pyelography, were of greatest aid in determining pathological conditions of the urinary tract and where it aided us in excluding this tract as the source of this trouble.

In 1876 the invention of the electrically lighted cystoscope by Nitze and Leiter revolutionized the previously existing crude and painful methods of inspecting the bladder. One can imagine the progress and refinement along such lines of investigation, when one compares the procedure of a forcible dilatation of the female urethra for the insertion of a tube with our modern almost painless cystoscopy.

The cystoscope has its greatest application in the study of abnormalities in the urinary tract where it plays an indispensable rôle in establishing an accurate diagnosis. A failure to avail oneself of its use often leads to error. Given a patient with symptoms referable to the genitourinary tract it would be folly to attempt to determine the existing pathological lesion without the employment of the cystoscope, just as it would be to classify a comatose patient as of uremic or diabetic origin without confirmation by a blood chemistry.

I shall cite briefly a few cases illustrating various lesions of the urinary tract where a diagnosis without cystoscopic study was impossible.

Case I.—A. W., male, aged sixty-five, was admitted to the hospital with a painless hematuria of several weeks' duration. On physical examination no abnormality was found; a lesion of either the kidney or ureters or bladder might have accounted for the bleeding. Cystoscopy revealed a benign papilloma which was subsequently fulgurated.

Case II.—J. M., male, aged fifty-three, was admitted with hematuria and pain in the right lumbar region. On examination there was found right costovertebral tenderness. Here again several conditions might have been responsible for this patient's complaint. Cystoscopy disclosed a papillomatous growth in the bladder, very suspicious of a beginning malignancy.

Case III.—S. A., female, aged forty, was admitted with pyuria, hematuria and pain in the right lumbar region. About two years ago she had had her appendix removed for chronic pain in the right lower abdomen and back. On physical examination a large, slightly tender right kidney was palpable. A diagnosis of infected hydronephrosis or of kidney neoplasm was considered. After pyelographic study we favored a diagnosis of neoplasm which was confirmed by operation.

Case IV.—R. S., female, aged forty-six, complained of pain in the back and hematuria. On examination we found two large irregular masses corresponding to the kidneys. We suspected that the kidneys were polycystic. Pyelographic study of one of the kidneys showed a filling defect of its pelvis, thus favoring our diagnosis. Autopsy proved this to be correct.

Case V.—H. S., female, aged thirty, complained of a mass in the abdomen. This mass was smooth and regular, about the size of a grapefruit at the level of the umbilicus, reaching several fingers' breadth below it in the median line. Several conditions were considered, including a fused kidney. A ureteral catheter was passed along the left ureter and on x ray found it entering the mass. The right ureter could not be catheterized. This was undoubtedly a case of a fused kidney.

The cases cited above are representative of some of the urological conditions where without cystoscopic study an attempt at diagnosis is merely a conjecture. A failure to avail oneself of complete cystoscopic investigation in suspected lesions of the urinary tract often leads to erroneous diagnosis. Even in the face of an apparent lesion of the genitourinary tract we should not miss the advantage of a means of study which will enhance the correctness and thoroughness of the study of pathological conditions and at the same time disclose anatomical defects.

*From the services of Dr. Henry Roth and Dr. L. Miller Kahn, Lebanon Hospital, New York.

The following cases were incorrectly diagnosticated owing to lack of complete cystoscopic examination.

Case VI.—L. C., female, aged forty, complained of pain in the back with hematuria. Eight months before, cystoscopy without a pyelogram revealed nothing. On physical examination there was right costovertebral tenderness. Admission diagnosis was renal stone and pyonephrosis. Operation disclosed a growth in the pelvis which proved to be a papillary carcinoma. A pyelogram would have been of considerable value and perhaps might have established a diagnosis. Such cases are seldom correctly diagnosed without a pyelogram.

Case VII.—H. M., male, aged fifty, was admitted with a history of retention of urine. The urine passed prior to admission was bloody. On examination there was found a large, regular prostate seemingly responsible for the retention of urine. Owing to the presence of a large quantity of blood and blood clots in his bladder, an attempted cystoscopy proved unsatisfactory. A suprapubic cystotomy revealed the presence of a carcinoma of the bladder.

Case VIII.—S. G., aged sixty-five, male, complained of retention of urine. On examination we found a large regular boggy prostate. The bladder was moderately distended. No cystoscopy was done. During the first stage suprapubic prostatectomy five large vesicle stones were discovered.

The last two cases emphasize the importance of cystoscopy in cases where diagnosis seems obvious and the possibility of the presence of multiple lesions in the genitourinary tract.

One or several attacks of renal colic was the chief indication in many of our cases where cystoscopy was necessary. In studying these cases we were disappointed by the lack of röntgenological evidence of stone in many cases where the symptoms and cystoscopic study warranted the diagnosis of ureteral calculus. Bearing in mind that approximately ninety per cent. of ureteral calculi are detected by means of our present day methods in x ray technic we were often inclined upon failure of the x ray to believe we were dealing with some other lesion of the urinary tract which simulated a calculus.

Ureteral stricture is a common lesion and is being recognized as responsible for many unaccountable and obscure abdominal pains. Hunner has found this condition in two thousand patients in the past several years. Its symptomatology may be so diverse as to mimic other abdominal lesions. Pain is the chief symptom, more often local over the ureter near the pelvic brim or over the kidney. If the stricture is marked there is often stasis of urine, hydronephrosis and infection. Dietl's crisis may also occur. Many cases of prolonged infection of the pelvis of the kidney have been shown to be caused by stricture of the ureter, as evidenced by the fact that a cure resulted after gradual dilatation of the strictured area. This lesion should always be suspected in cases of pyelitis which do not respond to ordinary treatment provided no calculus is present. Strictures can only be diagnosticated by ureterogram or bulb test.

The cystoscope should be more generally used by the general surgeon as a means of making certain that the urinary tract is not the offender. More accurate diagnoses would result and unnecessary surgical explorations of the abdomen would be less often resorted to if such diagnostic accessories were more commonly used.

The relationship of the appendix to the right kidney in pathological states has often been the subject of discussion. It is well known that lesions of the right kidney and ureter may simulate a lesion of the appendix and vice versa. Some of the patients sent to our hospital to be operated upon for appendicitis were found only after cystoscopic study to have lesions of the urinary tract. Occasionally we see a patient with ureteral colic who has already been operated upon for chronic appendicitis when a thorough investigation might have disclosed the true nature of the condition and an unnecessary operation would have been avoided. Renal or ureteral stones on the right side cause referred pain to the gallbladder and appendicular regions. On the left side the pain may simulate anginal attacks. In 294 cases of renal and ureteral stones Braasch found the pain referred to the right upper quadrant in fifteen per cent. and to the right lower quadrant of the abdomen in nine per cent of the cases. This emphasizes the need of more accurate study and differentiation to determine the source of the trouble. X ray shadows in the right upper quadrant of the abdomen may be caused either by stones in the gallbladder or kidney and the only means of differentiating their location is by pyelographic study.

Renal colic is known to simulate other abdominal lesions, such as intestinal obstruction, perforation of a gastric or duodenal ulcer, etc. It would undoubtedly be to the advantage of the patient if the physician approached an obscure case of cholelithiasis or chronic appendicitis with a more conservative viewpoint giving full value to the advantages to be gained by a careful investigation of the urinary apparatus before operation. The following cases illustrate with what difficulties one may be confronted:

Case IX.—M. S., male, aged thirty-eight, was taken ill suddenly with abdominal cramps and pain in the right lumbar region. The following day he vomited and had diarrhea. The pain was more severe now in the right lumbar region radiating to the penis; bloody urine was passed. On examination there was tenderness in the right lower abdomen and right lumbar region. When the patient entered the hospital one week later he presented a very large tender mass beginning in the right lumbar region palpable anteriorly and reaching down to the iliac fossa. Even now the diagnosis still rested between a pyonephrosis and an appendicular abscess, the latter diagnosis being favored. Such an opinion was strengthened by cystoscopy with x ray which revealed normal sized kidneys with normal urine from both. Operation confirmed diagnosis of appendicular abscess.

Case X.—B. G., female, aged forty, complained of vague and indefinite pain in the right upper quadrant with no radiation and no relation to meals. She was thought by the family physician to have chronic cholecystitis. No cystoscopy was done. At operation a normal gallbladder was found and in search for other lesions to account for the pain a prolapsed freely movable light kidney was discovered which was undoubtedly responsible for her complaint.

NEW YORK, WEDNESDAY, JUNE 2, 1926

Psychoendocrine States

EDWARD HUNTINGTON WILLIAMS, M.D.
and CLIFFORD A. WRIGHT, M.D.
Los Angeles

"This is the age incontrovertibly of fads," says Dercum. But endocrinology is not included in this term. Indeed, so far afield from faddishness does the subject of ductless glands seem to this same authoritative writer, that he includes even such vaguely pathological functional conditions as the psychoneuroses in the psychoendrocrine[1] category. Which shows courage as well as wisdom.

It has been pointed out by Biedl that, whereas formerly all organic correlation was assumed to be nervous, the modern conception is that the nervous relation is induced by chemical action—that chemical action precedes impulse. And this, if true, applies to the nervous mechanism concerned in abnormal as well as in normal cerebration.

In the process of evolutionary development, the endocrine system preceded the nervous; and impulses were sent by the comparatively slow chemical messengers long before the nerve telegraph system was established. The two systems now work together, the nervous mechanism for the purpose of getting quick action apparently as in cases of emergencies, and the chemical response requisitioned for sustained effort. This is suggested by the close anatomical affiliation between such glands as the adrenals and the sympathetic system, the adrenal medulla being part of the chromaffin system embryologically. And this anatomical and clinical suggestion seems to be verified in certain abnormal mental states in which there is involvement of the adrenals, either as primary or as secondary factors.

In many acute infections, for example, there is an increase in the amount of adrenalin in the circulation; and certain manic syndromes, both acute and chronic, give a picture of infectious states, with increased adrenal action. Neurasthenia and hypochondriacal states, on the other hand, seem hypoadrenal in character, possibly following hyperstimulation of the adrenals by some infectious process.

Of course, demonstrable endocrine disturbances, in some degree and at some stage of the syndrome, are present in many of the psychoses. But in what relationship?—cause, effect, or merely coincidental?

The correct answer to this question involves one of the most important problems in psychiatry—suggests the possibility of raising this somewhat inchoate department of medicine to the scientific level of the other fields of diagnosis and therapeutics. And the fact that endocrine misfunction is an etiological factor, in one or more of the psychoses, is a most gratifying beam of light in a somewhat hazy field. It is an excellent weapon against charlatanism.

Fortunately, the weight of clinical evidence seems to indicate that endocrine action is etiological. Physical and metabolic abnormalities are usually present in psychopathic patients before the mental symptoms appear; and such patients present anatomical stigma to the extent of seventy-five per cent., according to Saiz. These, and such patent physical abnormalities and the toxic conditions that accompany certain psychoses, are much more suggestive of cause than of effect. And such endocrinologists as Dercum, Lisser, Bandler, Timme and others are very definite in the statement that endocrine imbalance is responsible for some of the psychoses. Surely no one today doubts that the mental state seen in myxedema cases is caused directly by an underacting ductless gland. And if this is true in this exaggerated form of hypothyroidism, surely it is a reasonable deduction that less degrees of thyroid abnormality, or other forms of it, may be responsible for other types of mental aberrations.

Yet there is no more reason to associate psychoendocrine conditions with the thyroid ductless gland, than with several other of the group of endocrine organs. Indeed, there is some good clinical evidence to the contrary. For example, the observations of Foss and Jackson as to the incidence of mental disease to goitre in the Pennsylvania goitre belt near Danville, lead to the conclusion that, "insanity is extremely rare among the large number of goitre patients applying for treatment in this locality, there being no true insanity among the eight hundred patients studied." But the experience of these ob-

[1]Psychoendocrine is used as a term to express conditions for which there seems to be no other available single word or term. The word has been censored by no less an authority than Dr. Frank H. Vizetelly, editor of the New Standard Dictionary, at least to this extent that he writes: "If it is a term that satisfies you, meets your needs, you are within your rights to use it."

servers in this respect seems rather unusual, and is not in accord with our own observations and those of our associates in this, and the staff of the adjoining psychopathic hospital, where the percentage of goitrous insane patients is very much greater. And, in any event, even though it could be shown that an overactive thyroid does not often cause psychoses, this does not in any way affect the positive evidence that an underactive thyroid often does, as seen in myxedema cases.

However, the item of greatest interest and importance to us as clinicians is the determination as to whether certain kinds of endocrine misfunction is directly responsible for some kinds of mental distortions, psychopathic or psychoneurotic; and if treatment aimed to correct the endocrine abnormality will clear up the mental condition.

It is our belief, based upon personal experience and the experiences of our associates here and those reported by our confrères in other places, that one may reasonably expect to get better results by vigorous opotherapy in properly selected mental cases with manifest endocrine disturbances, than by any of the older methods of treatment alone, which did not consider endocrine imbalance as an etiological factor.

To be sure, we do not as yet cure most cases of dementia precox by organotherapy. Neither do we cure most cases of general paresis by vigorous antiluetic treatment. Despite which, no one these days, I suppose, doubts the luetic cause of paresis. On the other hand, there are many patients with paresis that are greatly benefited, even though not cured, by antisyphilitic treatment. And, similarly, many cases of dementia precox, and other psychoendocrine cases, are markedly improved—some of them seemingly cured— by glandular treatment. And, since the older conceptions of the causes of mental disorders and the older forms of treatment based on these conceptions were so unsatisfactory in the all important matter of results, it seems to me that this newer field is entitled to an exhaustive, intelligent trial. Particularly so, since the older one has so very little to offer.

The following are some cases that fall in the category under consideration, some of which, we venture to believe, fared better under the newer treatment given them than they would have done under the methods of treatment in vogue everywhere prior to the advent of opotherapy:

Case I.—A woman of thirty-nine was in a borderline state, with a history that indicated a gradually increasing mental instability that eventually would become a true psychosis in all probability, and a physical condition that was endocrine beyond question. Her complaint was essentially one of fear—she said she did not know what she was afraid of, or why. Her family history was negative. She menstruated first at eleven or twelve, periods regular and painless at first, later delayed about two weeks, profuse, and lasting about ten days. Married when fifteen, but had never been pregnant. For the last ten years she had been having nervous chills and gradually becoming more nervous and emotional (apprehensive). She said the chills "began in her stomach and went to her heart and then all over her," and she sometimes "lost herself." Had pain in the back of head, lips felt numb, and also a numbness or lack of feeling at the end of the spine when she sat. For the last four years had had frequent dull headaches. She had cold spells at night. These symptoms were not all constant, but were becoming more frequent.

Examination showed a woman much overnourished —girdle type of obesity. Skin was dry and smooth, nails brittle, hand of the pituitary type. Full across the back of the neck, hair turning gray, large round head and face. Teeth were small, about the size expected in a person of fifteen. Tonsils slightly enlarged, appeared to be infected. Thyroid palpable, possibly slightly enlarged. No tremors of extended fingers. Skin of extremities was cold. Heart and lungs negative. Blood pressure 150-90, pulse 86.

Her mental state was one of mild, but increasing, apprehension—of worry about herself, without great depression. During the last four years she had gradually developed ideas of a paranoid type without foundation, which she recognized as delusions, but which were gradually increasing in intensity, and had now reached a state where her insight was not quite clear—she did not always recognize them as delusions. Meanwhile her physical symptoms were gradually increasing, presenting a syndrome that an endocrine type as generally considered at present.

Pituitary products with calcium phosphate were prescribed, and diet regulated somewhat. After thirty days the symptoms showed improvement, she was less fearful and was losing weight. Three months later she was almost entirely free from her mental symptoms, had good insight, and was cheerful and hopeful. She had lost twenty pounds. She has kept up the treatment faithfully. She declared she felt well.

Case II.—That of a woman of forty, who became greatly depressed to a degree in which she attempted suicide, and whose feeling of dissociation became actually psychopathic, requiring hospital care. Family history negative. Married at eighteen, three children, no miscarriages. The beginning of her mental state dated several years back, and was very gradual in its approach. Examination showed a woman very much overweight (two hundred pounds, five feet four inches) the distribution of her fat suggesting the pituitary obesity of Timme. Thyroid slightly enlarged. History of goitre in childhood. Nails brittle, ridged. Heart and lungs negative. Nothing of special note, except a striking condition of hypotonia and muscle flabbiness—the muscles had what might be called a mushy feeling—and a sluggishness in her mental and physical reactions. She was given adrenal and pituitary products with thyroid. At the end of a month her blood pressure had gained thirty points systolic (from 110 to 140) and, although she had lost thirty pounds in weight, her muscle tone was noticeably improved.

Her mental condition was much better—mind more active, clearer, and with less dissociation, and good insight into the nature of this condition. After four months she became perfectly clear mentally, with only an occasional hint of the old dissociation. And meanwhile she had lost a total of sixty pounds in weight, with a decided improvement in muscle tone, actual strength, and endurance. She was originally troubled with insomnia, but this cleared up in six weeks, with only an occasional restless night. She is still under observation, but not treatment.

The suggestive points in this case are the type of

psychosis, which did not seem to fit exactly into any of our present accepted classifications, and the seemingly close association of this condition and the metabolic disturbance.

CASE III.—Mrs. W., a woman of twenty-four, married three years, no children, no pregnancies. Family history good; personal history—usual children's diseases, no severe illnesses. Menstruation began at fourteen, irregular, scant, at times painful. A fine looking young woman, intelligent and of the cultured type.

Three years ago, shortly after marriage in which her sexual life seems to have been normal, she began having periods of insomnia, a feeling of nervous apprehension, and gastrointestinal disturbances. Menstruation was scant and irregular. Began gradually to have difficulty in controlling the action of her legs and arms—the limbs would draw and assume grotesque attitudes so that at times she could not walk or direct them—a catatonic condition. She became hypochondriacal, thought that her gastrointestinal organs were distorted, and would not eat anything but liquid foods of certain kinds. Lost twenty-six pounds in weight. Mentally, seemed to have definite delusions, was introspective to the exclusion of almost everything else, imagined that she did not sleep at all—had not slept for five months, she declared.

The patient's feet and hands were cold; blood pressure was 103-80; skin was cool and clammy; arms and legs were resistive on attempts by examiner to move them; reflexes were normal. Uterus was small, almost infantile in type, but in normal position. She was tall, well formed, and of pleasing appearance.

The picture presented by this young woman was that of beginning dementia precox. She was given ovarian substance, whole pituitary, and thyroid by mouth, and ovarian extract twice weekly hypodermically. Circumstances were such that her home surroundings could not be changed, but the treatment was carried out precisely. She began to improve within three weeks.

In five months' time the patient's delusions had disappeared and were recognized by her as delusions. She was eating well, was no longer hypochondriacal, had gained twenty pounds, was hopeful and cheerful, doing most of her own housework. Slept six or seven hours at night and one or two hours in the afternoon. Menstruation less irregular, more profuse, not painful. She was cheerful and hopeful. The spasticity of her legs was still present, but much less than when first observed, and she had much better muscular control—could walk readily and did so several miles each day. She acted and appeared normal, a striking contrast to her first appearance the coldness and clammy feeling of the extremities has almost disappeared, although the left foot still bothered at times. Her blood pressure was 120-85. She was keeping up the treatment very conscientiously.

There is no doubt in our minds that this patient was positively and definitely benefited by the treatment. When first examined she presented a picture of a person, the type seen hundreds of times by all clinicians, that heretofore almost invariably defied treatment, and developed permanent and characteristic mannerisms, negations, and delusions, with final mental deterioration.

Desiccated Gonadal Substances*

HERMAN SHARLIT, M.D.
HELEN MILLER NOYES, M.A.
and K. GEORGE FALK, Ph.D.
New York

It is the aim in the drying of endocrine glands for therapy to preserve unchanged as far as possible all their chemical elements. Especially so with the preparation of such materials as have as yet debatable therapeutic properties and from which no characteristic chemical substance has been isolated. In order to estimate the residuum of "freshness" in tissues after desiccation, it is the practice to determine both quantitatively and qualitatively the changes in the labile properties of these tissues. To the extent to which these are preserved may we consider the tissues "fresh."

There was presented elsewhere (1) a theoretical consideration of the problem of dehydrating endocrine glands, and some simple chemical estimations (2) calculated to throw light upon the effect of dehydration of tissue by different methods. The effect of dehydration upon a very labile property of tissue, namely, the enzyme action, is presented here.

Enzymes are found in living matter. They have not as yet been isolated in pure form, and are known only by the effects they produce. Their behavior and the conditions able to inactivate or destroy them, stamp enzymes as possessed of very sensitive constitutions. They are similar to living organisms with respect to the ease with which they may be inactivated. In a broad sense, enzyme action as studied *in vitro* may be regarded as a close approximation to the chemical study of living processes in the laboratory. We can readily appreciate from this that the enzyme action of tissues after treatment for preservation forms an exacting test for "freshness."

Falk, Noyes and Sugiura (3) (4) (5) by a method of collecting data on the esterase (lapase) action of fresh tissues developed a method which may be used in the study of desiccated endocrine products. They determined the hydrolyzing value of different organs and tissues in several species of animal on ten esters under controlled conditions. An esterase

*From the Plaut Fund for Research in Internal Medicine, Harriman Research Laboratory, The Roosevelt Hospital, New York. Read before The American Society of Clinical Pathologists at Philadelphia, Pa., May, 1925.

enzyme hydrolyzes an ester with the production of free acid. By titration of the free acid formed with standard alkali, quantitative values for the esterase actions are obtained for the given experimental conditions.

The endocrine products of three manufacturers were used. Each of these products was stated to be desiccated *in vacuo* at a temperature not over body heat. The several sets of products from each of these manufacturers purchased about a year apart were studied. A paper (2) in which the ether soluble portion and several nitrogen fractions of the earlier tested. The values in the table indicate that products A have greatest esterase action. The absolute measure of this appears to parallel the amount of soluble nitrogen. This parallelism is strikingly brought out by the decreased order of magnitude of esterase action of the two samples of orchitic substances of products B and C, which order is accompanied by similar changes in the values of the soluble nitrogen.

It is not the purpose of this report to adduce evidence as to the relative therapeutic value of these three products. Such properties must still be determined in the clinic (1A). An earlier report on

(I) Results on first lot of material. (II) Results on second lot of material.

batch of materials were reported led to the opinion that products A probably were prepared after a better technic than B and C because a higher percentage of the total nitrogen soluble in water remained in them. Table I shows that in a similar analysis of the second lot of gland substances from these same manufacturer's products A still possessed the highest water soluble nitrogen fraction. It may here be pointed out that products A were not defatted, products C were all defatted and only the orchitic substance of products B was defatted.

It was expected that such influences, in the process of dehydrating glands, destructive of the tissue enzymes, might reduce quantitatively the esterase action on each of the ten esters used. And, since equivalent amounts of each of the esters were employed in this experiment it was deemed permissible to combine the absolute actions upon the separate esters in a single measure—this measure being the sum of the absolute actions upon the separate esters in each series for each endocrine substance. Table II gives these absolute values for the three ovarian substances —whole ovary, ovarian residue and corpus luteum, and for the orchitic substance for products A, B and C. This table also shows the percentage of water (alkaline) soluble nitrogen for each of the samples products A, B and C indicated, because of the greater value to the soluble nitrogen, that A was prepared by a technic safer in the sense that it caused less change in the fresh material. This enzyme study on the same products leads to the same conclusion. Those interested in endocrine therapy, especially with materials whose clinical value is in question, must realize that differences in the method of manufacture of these materials result in their being supplied with different chemical mixtures but labeled with identical names.

The authors wish to thank Mr. Isaac Lorberblatt for determining the nitrogen and fat values.

Some Clinical Aspects of Human Sex Gland Maldevelopment and Its Possible Relief

MAX THOREK, M.D.

Chicago

A case which I had the opportunity of examining about a year ago brings up the interesting question of that type of sex gland maldevelopment known as pseudohermaphroditism. In this case the examination of a boy revealed the fact that I was dealing with a pseudohermaphrodite. The general clinical characteristics are well illustrated in the accompanying photographs. (Figs. 1, 2 and 3.)

On looking into the history of this patient I found that originally the sex was considered female. The school records indicated that the socalled girl was seven years and three months of age, but that she had the physical development normal to a twelve year old child. Mentally, however, she was rated at seven years. She could read very little and her mathematical accomplishments consisted only of an ability to count a row of objects. The child had a sluggish temperament, was always slow and brief in response, volunteered nothing and spoke in a hoarse, harsh voice. Generally she showed the shutin type of personality, unemotional but with a dazed expression in the eyes reminiscent of the epileptic. She was classed with subnormal children.

FIG. 1.—Feminine characteristics of patient.

The development of the penis had apparently caused the child's sex to be doubted and "she" was changed to a boy and given a boy's name. Some time after this the case came under my observation.

The interesting point in connection with hermaphroditism is that both female and male gonads may coexist in the same individual, and that sex manifestations are matters of the functional secretions of certain cellular tissues rather than the anatomical or morphological distribution or arrangement of organs. Some assert that man is bisexual and that every normal human male and female retains cells of undifferentiated accessory sex organs of the opposite sex; i. e., that there is no such thing as a pure male or female, but that each contains the elements of the other sex. The secondary genital organs have a bisexual origin and each adult shows some degree of hermaphroditism.

The matter of development of secondary sex characters in a masculine or feminine direction is one that depends upon the predominance of masculine or feminine internal secretory glandular tissue. The occurrence of heterologous sexual organs, or other characteristics usually associated with a particular sex, is explained on the supposition that the suppressed or dormant secretory portions of the sexual glands belonging to the opposite sex have attained some activity or ascendancy.

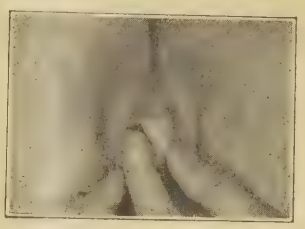

FIG. 2.—Pseudohermaphroditic genitalia disclosing labia, penis, urethra, vaginal cloaca, and pudendal aspect of external genitalia when in the lithotomy position with labia spread.

Hermaphroditism is to be distinguished from eunuchoidism in which, in the male, for some congenital or constitutional reason, the sex glands fail to develop normally, but in which there is no direct manifestation of duality of sex characters. I have seen several cases of this type in which the external genitalia were of infantile type, as may be seen in the accompanying illustrations. (Figs. 4 and 5.) The eunuchoid lacks the sexual vigor and potency of the normal individual but otherwise passes for a male.

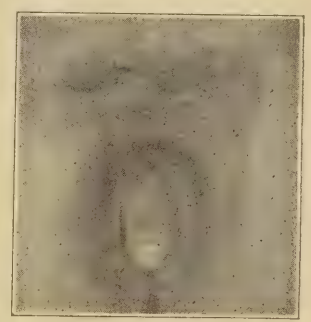

FIG. 3.—Size of penis and its position covering the vaginal cloaca.

The hermaphrodite, on the other hand, is a sexless being, a condition which entails peculiar physical, mental, moral and legal consequences. The constant brooding and introspection to which these unfortunates are subject frequently make their existence miserable and they often are driven to suicide. Because of this it is a matter of the gravest importance that just as soon as any doubt arises regarding the true sex of a child, parents and guardians should take immediate steps to have one definite sex established. In this regard I consider that, after taking

FIG. 4.—Eunuchoidism. Observe development of breast, and contour of body and genitalia.

every factor entering into a given case into consideration, a testicular or ovarian transplantation is of particular value, depending upon which sex elements predominate. In well selected cases and with proper technic not only does the transplanted tissue function and have its proper effect in developing and establishing the dominance of the proper characteristics, but there is good reason to believe that the transplanted tissue enables homologous tissue to develop. Thus Morris (1), in 1916, reported a case in which a scrotal testicular graft was apparently absorbed but at the same time the vestiges of the man's own testicles regenerated and began to grow, as well as the vestiges of the epididymis and cord.

I have fully demonstrated elsewhere (2) that testicular grafts are capable of becoming vascularized and functioning tissue, and that the secretions from such transplants produce the same biological effects as the secretions from normal testicular tissue, apart from spermatogenesis. Knud Sands's (3) experimental transplantation work proved that the implantation of one type of sex gland in the opposite sex caused development of both types of glandular tissue.

I believe that in pseudohermaphroditism an early sex gland implantation will not only develop the secondary sex characters, physical and psychical, appropriate to the gland implanted, but will help to develop the nondominant similar glandular element existing in the subject.

The same applies to eunuchoids with defective testicular development, a fact which has been clinically demonstrated. To neglect these classes of sex gland anomaly and not subject them to thorough study and every possible assistance is wrong both from humanitarian and scientific points of view.

FIG. 5.—Penis and scrotum of eunuchoid.

Endocrines in Blood Pressure*

WILLIAM LINTZ, M.D.

Brooklyn

In a disease like hypertension, whose ravages are responsible, directly or indirectly, for as many deaths as cancer and tuberculosis combined, if something new is brought forward towards lessening this frightful mortality, it certainly needs no introduction.

The use of antipituitary serum in hypertension, prepared by injecting the pituitary gland in a horse, precludes a direct or indirect endocrine causal relationship to blood pressure. Such a view has been shared by many medical authorities throughout the world. Everyone is acquainted with a very frequent form of hypertension due to hyperthyroidism.

In diabetes, where the islands of Langerhans are diseased, hypertension is not an infrequent occurrence. Insulin lowers blood pressure in these cases.

The hypertension which originates at the time of the male and female menopause is known to everybody. Fifty per cent. of the hypertension that I see in women can be traced to the menopause. I know of no better way of foretelling the approach of the female menopause than by the steadily rising blood pressure, providing there is no other palpable explanation; and this irrespective of the menstrual character at that time. The very best remedy that I know of for these women with hypertension of climacteric origin is the administration, by mouth, of five grains of corpus luteum three to four times daily.

Bruno Bellucio exposed the testicles to x rays, in men past sixty years of age, having a blood pressure of 180 and over; this destroys the seminiferous tubercles but leaves the interstitial cells of Leydig intact. In every one of his cases he obtained a marked reduction in blood pressure, both systolic and diastolic, sometimes as much as one hundred millimetres, which reaches its maximum at the end of ten days after exposure, and the blood pressure did not begin to rise until the end of twenty-five days. This is similar and harmonizes with the results of the Steinach operation in old people, where, as you know one of the effects is the decided lowering of blood pressure.

I wonder if the favorable results obtained by some clinicians in hypertensive cases, after exposing the tonsils to the x ray, may not have been due in reality to the fact that the pituitary shared in this treatment. I have tried this method of treament but obtained

*Delivered by invitation at a meeting held on April 19th, 1926, at the New York Academy of Medicine, before the Medical Association of Greater New York.

nothing but negative results. The pituitary was carefully excluded from receiving the x rays.

HYPERTENSION A COMPLEX PROBLEM

But unfortunately the problem is more complex. The endocrine glands are not the only factors in blood pressure. While it is true that a persistence of hypertension leads to arteriosclerosis, cardiac hypertrophy, myocarditis and chronic nephritis, it is equally true that some cases start from the onset as nephritis and hypertension develops subsequently. We must admit, however, that we may have both nephritis and arteriosclerosis without hypertension. There is a close relationship between hypertension, chronic nephritis and cardiac sclerosis, most probably because of a common, but as yet unknown, etiology and must be treated accordingly.

FOCAL INFECTION AND ALLERGY IN HYPERTENSION

In another group of hypertensions general focal infections play a vital rôle. I have observed another form of hypertension which is associated with allergy. Do not hesitate to give a hypodermic of adrenalin to an asthmatic with hypertension. You will find that not only will you relieve him of his asthma but also of his hypertension. I have frequently seen a drop in blood pressure of twenty to sixty mm. in such cases after the administration of adrenalin. I have seen patients who have been permanently relieved from their asthma, also permanently relieved at the same time from their hypertension. The blood pressure coming down from 200 to 160 systolic with a corresponding diminution in the diastolic pressure. In hay fever cases whose blood pressure ranged around 180-120 after three injections of pollens allergens the blood pressure came down to 145-80.

OXYGENATION IN HYPERTENSION

From these few remarks it is evident that hypertension has a manifold etiology and therefore cannot have a uniform therapy. Whatever its etiology I believe that when the last chapter on blood pressure will be written it will be found closely related to the process of oxygenation in the body. That is why when the insufficiency of the circulation improves there is a lowering of blood pressure, and only exceptionally is there an increase. For the same reason digitalis is not contraindicated in hypertension, but will frequently lower blood pressure considerably. I believe that the anemia of nephritis and infection, which plays such an important rôle in oxygenation, also is an important factor in hypertension. The vital capacity is very markedly diminished in hypertension.

It is interesting to note that the guanidin injections of Major not only raise blood pressure but markedly decrease the respiratory rate. Daily injection of ten c. c. of a twenty per cent. glucose lowers the blood pressure but also changes the colloidal condition of the serum, the viscosity of the blood and widens the capillaries. All these factors influence markedly oxygenation. Numerous other factors could be cited to support this theory. This for the present will be sufficient.

DIMINISHED LUNG SPACE IN HYPERTENSION

This does not explain the familiar hereditary nature of hypertension. I therefore had Dr. Siegfried Weinstein examine the respiratory apparatus of these patients, both fluoroscopically and radiographically and I was surprised to discover that the hypertension cases had small lungs, in proportion to their body weight when compared with other nonhypertension cases. Whereas hypertension cases had as low as one quarter square inch of lung space for every pound of body weight, the nonhypertension cases had frequently twice the lung space and even more for every pound of body weight.

The marked influence of small lungs upon oxygenation can be readily understood if we bear in mind that out of the four and a half litres of blood in our bodies, forty per cent. by volume is red blood cells, with a surface area of three thousand square metres, or a little less than a block; that every second the blood pumped into the lung, for the purpose of liberating the carbon dioxide and saturating itself with oxygen, has a surface area of eighty square metres. Oxygenation would certainly be very markedly influenced by such a diminution of aeration area as is evidenced in our cases of small lungs in hypertension.

The compensatory mechanism of our body plays an important rôle in all these conditions enumerated.

ANTIPITUITARY SERUM IN HYPERTENSION

My experience with the antipituitary serum comprises its use in about thirty cases. These patients were both ambulatory office cases and hospital cases. Some cases in this series must be discarded because for one reason or another they received but one or two injections or were not long enough under observation. About one half of the patients seemed to show a lowering of their blood pressure and consequent benefit.

According to the method of Dr. Laura, one and a half c. c. of antipituitary serum, prepared by injecting the pituitary gland in a horse and the serum obtained was injected into these patients every other day for about seven or eight doses. Great care was taken to obviate the usual allergic reaction when horse serum was applied. Serum reactions were rather infrequent both local and general. It is exceedingly difficult to judge therapeutic effects from any measure in essential hypertension, the only cases employed in our series, on account of the marked variability in blood pressure under normal conditions. Less than half the patients seemed to have been benefited somewhat by this treatment. I believe the results are encouraging and the serum should receive further trial.

CONCLUSIONS

1. Hypertension, directly or indirectly, is responsible for more deaths than carcinoma or tuberculosis combined.
2. There is a relationship between the endocrine glands and hypertension.
3. There is a relationship between nephritis and myocarditis and hypertension.
4. Infection, allergy and oxygenation play a vital rôle in hypertension.
5. Hypertension cases have a marked diminution in lung space as compared to their body weight.
6. The antipituitary serum is worthy of further trial in hypertension.

Goitre: Use and Abuse of Thyroidectomy and Iodine*

ISRAEL BRAM, M.D.
Philadelphia

The progress of goitre therapy has advanced with marked strides. Today, thyroidectomy, especially in those not suffering with Graves's syndrome, is a comparatively riskless procedure. Moreover, the resulting scar is almost invisible, an eloquent evidence of perfected surgery. Basal metabolic studies, formerly regarded as difficult and mysterious, are now the routine, and almost as commonly employed as the clinical thermometer. Thus, not only is diagnosis of thyroid toxicity made with precision, but the results of treatment are evaluated, and even prognosis can be discussed with intelligence by the aid of this laboratory device. In the field of prevention, the use of iodine seems likewise to be a boon to humanity, and whereas formerly a large percentage of school children seemed doomed to acquire goitre, the systematic administration of minute doses of iodine appears to succeed in reducing this percentage. The optimist has much to be thankful for in advances made in the control of thyroid conditions, a progress which is only comparable to that in treating diabetes mellitus.

These truths, however, cannot be stated unqualifiedly. As a result of a prolonged study of this problem, with clinical observations of over nine thousand goitre cases, I am forced to the conclusion that despite the perfection of thyroidectomy and the lowering of its mortality rate, this measure is often abused. Despite the use of iodine in the therapy of goitre, this measure, too, is largely abused, a fact to which I have called attention for some years, and to which others are now likewise calling attention. The perfection of goitre therapy can only be reached when thyroidectomy and iodine cease to be abused.

USE OF THYROIDECTOMY

Generally speaking, thyroidectomy is the only successful procedure in the treatment of goitre essentially neoplastic in nature. Such encapsulated tumors as adenomata, cysts, fibrous goitres, and various combinations of these, require thyroidectomy. Again, such unusual pathological conditions of the thyroid as diffuse adenomatosis, malignancy, and inflammations, usually require surgical attention. In toxic adenoma the surgeon is indeed the lifesaver of the patient. Parenthetically speaking, cures of toxic adenoma by thyroidectomy are frequently checked up in surgical statistics as recovery from exophthalmic goitre, an unfortunate circumstance leading to erroneous implications. Surgery performed on adenomatous and cystic goitres is not only productive of the desired cosmetic result, but is likewise a prophylactic against malignant changes, since it is well known that the vast majority of carcinomatous goitres occur secondarily to innocent neoplasms. It is here that thyroidectomy has its greatest use.

ABUSE OF THYROIDECTOMY

On the other hand, why do we observe so many instances of recurrence of goitre following even expert thyroidectomy? The answer is simple: Thyroidectomy was performed upon an unencapsulated thyroid enlargement in which the swelling was not a local condition but a manifestation of changes occurring elsewhere in the body. Nature resents thyroidectomy in simple thyroid hypertrophy, colloid goitre, puberty hyperplasia, and more especially in the hyperplastic thyroid of exophthalmic goitre (Graves's syndrome). It is these four types—not truly neoplastic in nature, but nonencapsulated thyroid swellings, that should be designated as nonsurgical goitre. Surgery here is usually a failure, and regeneration of goitre following thyroidectomy is very frequent. Unless the mass is substernally located, or presents an adenomatous or cystic admixture, these four types of thyroid enlargement require nonoperative measures by the medical attendant who is well enough equipped to seek and eliminate individual cause and eradicate the thyroid enlargement by methods tried and proved successful. Unfortunately, the number of internists capable of effecting recovery, especially in sufferers from exophthalmic goitre or Graves's disease, is not great enough to offset the psychology of immediate though temporary results produced by brilliant thyroidectomists, and so the abuse of thyroidectomy will probably stay with us for a while.

USE OF IODINE

Iodine stands foremost among drugs discussed in the treatment of goitre. No one questions its efficacy in the prevention of a large number of goitres in so-called endemic districts where it is proved that there is a deficiency of iodine in food, air, or water. Also there is no doubt of the curative value of iodine in a percentage of small goitres occurring in these districts. On the other hand, very considerable harm is wrought by undue enthusiasm on the part of the protagonists of iodine therapy, with resulting indiscriminate use of this drug by busy general practitioners, and even by the laity. Things have come to such a pass that at the recent meeting of the American Association for the Study of Goitre[1] the members went on record as being opposed to the use of iodine as it is employed today.

ABUSE OF IODINE

Greater conservatism in the use of iodine would be exercised if it were borne in mind that, 1, iodine is a potent drug, to be employed only after very careful study of the case in hand; 2, endemic goitre is not necessarily due to iodine deficiency, but as McCarrison and others have pointed out, to unhygienic surroundings, microbic infection of food or water, and many other factors as well; 3, areas regarded as goitre belts likewise present sporadic goitre, which is rarely due to iodine deficiency but often to such complex causes as heredity, infectious foci, intestinal autointoxication, the premenstrual status, adoles-

*Address delivered before the Williamsburg Medical Society, Brooklyn, February 8, 1926. (From the Bram Goitre Institute.)

[1]At this meeting (Louisville, Kentucky, February 3, 1926) and at the preceding annual meeting (Bloomington, Ill., January 29, 1925), I had the pleasure of addressing the organization, and in discussion with a large number of the members, I found almost universal antagonism to iodine therapy, even in socalled goitre belts.

cence, pregnancy, the menopause, and diseases of the gonads, all of which can hardly be cured by the administration of iodine; 4, clinical results prove that iodine employed indiscriminately is capable of making small goitres larger and simple goitres toxic; and 5, since the publicity given iodine as a remedy for

goitre, we have had more goitres, especially toxic, in our midst, than ever before.

In colloid goitre, how can one expect to clear up the mass through iodine, when this drug is known to bring about an increase in colloid? This is why many colloid goitres treated with iodine become larger and produce pressure symptoms and occasionally symptoms of hyperthyroidism. Simple thyroid hypertrophy likewise becomes larger in many instances when treated by iodine, approaching colloid goitre in size by sheer increase of colloid content.

To those who would advocate thyroidectomy in the treatment of exophthalmic goitre, the preoperative use of iodine is useful, tending to lower the operative mortality rate and reduce postoperative crises. Since iodine tends to cause a reversion of the hyperplastic goitre to the colloid state, there is a reduction of thyroid toxicity. But this is temporary. Unless the sufferer from Graves's disease is luetic, the continued use of iodine with a view to cure leads to disappointment. While a large portion of the thyroid ceases to be hyperplastic, a sufficient remainder becomes more toxic than ever, ultimately leading to a clinical picture of crisis. The thyroid, a detoxicating organ, has enough to do to fight the known and unknown poisons in the patient's economy; is it any wonder that the addition of another potent poison, iodine, is met with resentment? The continued use of iodine in a Graves's disease subject may lead to a condition even more dangerous than a crisis. The resulting colloid infiltration may cause the goitre to increase to such a size as to endanger

life through asphyxia. I have seen several such instances requiring emergency thyroidectomy.

SUMMARY

Briefly stated, the treatment of goitre amounts to this: when to thyroidectomize, when to use iodine, when to use x rays, and when to use other measures. Through scientific and lay periodicals the profession and laity have unfortunately been accustomed to regard goitre as a lump on the neck requiring either operation or iodine for its removal. This state of mind hinders progress. Simple hypertrophy, colloid goitre, puberty hyperplasia, and the hyperplastic thyroid of exophthalmic goitre, are local expressions of erroneous processes of more or less complex nature occurring elsewhere in the body. Unless these processes are corrected, neither thyroidectomy nor any other local procedure will cure the "lump."

Especially is this true of exophthalmic goitre where, aside from the hyperthyroidism (or is it dysfunction?) of the thyroid, there occurs hypofunction of the pancreas, posterior pituitary, parathyroids, suprarenal cortex, and gonads; hyperfunction of the thymus, anterior pituitary and suprarenal medulla; there is a dysfunction of the vegetative nervous system, in which now sympatheticotonia, now vagotonia dominates the clinical picture; and the emotional centres are constantly in a state of abnormal alertness. Add to this the fact that sufferers from Graves's disease have had a lifelong neuroendocrinopathic makeup, how can we expect genuine recovery of this most complex syndrome by the mere cutting off the lump on the neck?

The time has come when men who treat goitres in great numbers should get together and compare notes. There should be a purging of preconceived notions, an elimination of pet hobbies, and especially a foresight that will substitute for immediate results with mere improvement of the patient the more important consideration of complete, permanent recovery with unequivocal restoration to health and happiness. It is thus that we will eliminate the goitre clientele from chiropractors, Christian Scientists, and other cults which are a reflection upon the medical profession and an affront to human intelligence.

1633 Spruce Street.

The Diagnosis and Treatment of Goitre

ARNOLD S. JACKSON, M.D.
Madison, Wisconsin

The subject of goitre is complex, but the problem of prevention and treatment has become such as to require the universal application of the same general principles. The opinion has been expressed that goitre as seen in New York state differs from that seen in Wisconsin or other middle or far western states. This idea has been ill founded since an adenomatous goitre seen in one section of the country is pathologically the same as that seen in another locality. That the incidence varies in different regions is not disputed. For instance, the number of girls afflicted with colloid goitre in New York city is much less than the number having goitres in Syracuse and other parts further inland. In Wisconsin seventy-five in every hundred young women in some districts have colloid goitres. This high ratio is observed in many middle and far western states. In the great northern half of the United States from the Atlantic to the Pacific, however, there are few localities that are not concerned with the problems of goitre. Not only villages, but cities and even states are now taking up the fight to check the spread of this disease.

Tuberculosis and cancer combined affect a small portion of our population as compared with the millions suffering from goitre. Until the past few years the spread of goitre has been such that if unchecked, conditions might in time resemble those in Switzerland, where statistics have shown that one of every six recruits for the army has been rejected because of a goitre or some disease due to goitre. Certain it is that there has been a rapid increase of goitre in the younger generation. The incidence of cretinism and feeblemindedness has likewise been on the increase. It is fair to assume that if the spread of goitre is not checked, future generations would give rise to much higher percentage of these diseases. In Switzerland, where goitre has prevailed for many generations, there has resulted a great number of mentally deficient children. Consequently the problem that concerns us is not one of merely local interest but of national importance. It is a question not only of serious social but of economic loss as well.

In order then that various sections of the country may not only develop plans for prevention but may also compare the results of treatment, it is essential that there be a common understanding regarding the classification and treatment of goitre. Probably more mystery has surrounded this subject, not only in the minds of the people but in the profession as well, than any other topic in medicine. For years the text books and medical schools have offered such complicated classifications of goitre and such ill founded theories as to treatment, that the majority of physicians have been either sorely perplexed or in utter disagreement.

It remained for Plummer to clear up a great deal of the confusion that has surrounded this subject. When he clearly showed in 1913 that exophthalmic goitre and toxic adenoma were two distinct clinical entities, he at once greatly simplified the question of diagnosis. Yet his deductions have been slow to permeate and it has only been in recent years that this differentiation has been generally appreciated. Even today some of our leading authorities as well as many in Europe do not acknowledge or appreciate the importance of Plummer's classical studies.

In order, then, properly to diagnose and treat goitre one must have a clear understanding of a simple classification of thyroid diseases. Such a classification is suggested as follows: 1. Colloid. 2. Adenomatous; a, nontoxic; b, toxic; c, iodine hyperthyroid-

ism. 3. Exophthalmic. Other diseases: tuberculosis, syphilis, actinomycosis, myxedema, hypothyroidism, and thyroiditis (acute, chronic, purulent).

We are at present concerned only with goitre, and will outline the main diagnostic points.

Colloid goitre.—This type of goitre is commonly seen in girls between the ages of ten and twenty throughout the goitre area. In some districts as high as seventy-five per cent. of the girls between the ages of sixteen and twenty show rather marked symmetrical enlargement of the neck. In former years this abnormal condition was frequently termed a physiologic enlargement and parents were frequently advised by their physicians to disregard this condition which in time would disappear. In spite of the great increase of knowledge on this subject, I see almost daily instances where this same advice is being given. It is true that a small number, possibly twenty-five per cent. of these colloid goitres, do recede after the period of full growth and development has been attained. In the remaining neglected colloid goitres, however, there develop adenomas, an effort on Nature's part to compensate for the unsatisfied demand upon the thyroid for thyroxin by the body tissues. Consequently to safeguard against the development of adenomas, every girl living within the goitre area should be placed upon prophylactic doses of iodine, even though there is no apparent enlargement of the gland. There is no harm in giving such treatment to boys, and it is especially indicated in developing colloid goitres.

There should be little difficulty in differentiating the colloid from the other types of goitre. Occasionally one is called upon to rule out a possible beginning exophthalmic goitre. The gland is symmetrically enlarged in both types, the patient may be nervous, complain of palpitation and tachycardia, weakness, insomnia and may even present a tumor. Exophthalmic goitre may be eliminated by the absence of characteristic points in the history. A rather rapid weight loss accompanied by a good appetite is typical only of exophthalmic goitre. In the latter condition only may be found thrills, bruits, a high pulse pressure, exophthalmos, a true quadriceps weakness, and a peculiar type of restlessness and nervous instability. The basal metabolic rate may register twice or even three times normal at a first test in a nervous young girl, but if accurately determined and checked it will be found to be constantly high and increasing in exophthalmic goitre.

More can be accomplished in the prevention of colloid goitre than in the actual treatment of this condition. Consequently, if results are to be satisfactory, treatment should be begun at the age of eight or ten. Small doses of iodine should be administered weekly throughout the school year. In my experience the iodostarine tablet containing ten miligrams of iodine has given the most satisfactory results. When the colloid goitre has actually developed it will be necessary to double this dose. The old custom of administering iodine in the form of unpalatable liquids, large tablets or by local application, in large doses and for short periods of time is passé. There is no objection to giving children salt containing iodine, but iodine should not be administered in wholesale form to the people. It has been my policy to urge that iodine in some form be given to every child in the goitre belt, but that the child be under the observation of his family physician while taking the medicine. Some health workers who do not happen to be physicians are urging iodine on the people in any and every form, telling them it is a food and not a drug. I should like to introduce them to some of the patients with iodine hyperthyroidism I have had to treat.

Adenomatous goitre.—This type of goitre usually makes its appearance between the ages of twelve and twenty in neglected colloid goitre. There is an asymmetrical enlargement of the gland; one or more nodules may be palpated. I believe that all adenomatous goitre have their inception during youth, although they may not become apparent to the patient until in later life. Once an adenoma has developed, all the iodine in existence or any other form of medicinal treatment will not remove it. I realize that this statement is in contradiction to a view that has been generally taught and accepted. Otherwise why have so many members of the profession persisted in giving iodine to persons with adenomatous goitre? Merely reducing the size of the goitre by causing the colloid to melt away should not be sufficient grounds for risking iodine hyperthyroidism.

In children, when adenomatous goitres have already developed, iodine may be given in small amounts. They should be observed at least every three months. In these cases iodine may serve to retard and check the growth of the adenomas by placing the gland at rest.

The various types of goitres classified in text books as cystic, calcareous, hemorrhagic, etc., are all merely degenerations of the adenomatous goitre. Several changes may be found in the same goitre.

Because of the fact that about two cases in every hundred become malignant, because one in five becomes substernal, causing pressure symptoms, and because in time about fifty per cent. become toxic, I advise that all adenomatous goitres of any size should be removed after the age of twenty-one. Because of pressure symptoms or disfigurement it may be necessary to operate before this age, but there is an increased tendency to recurrence.

Toxic adenomatous goitre.—If left alone, adenomatous goitres seldom give rise to toxic symptoms before the age of thirty-five. The average age at which toxic symptoms appear is forty-four. About one in every four adenomas becomes toxic before the patient reaches fifty years of age. An adenoma is present an average of sixteen years before the onset of toxic symptoms. These symptoms develop so slowly and gradually that the patient may not be aware of anything serious until permanent damage to the cardiorenalvascular system has occurred. Myocardial degeneration occurs frequently.

The history of these patients shows that there is gradual progressive loss of weight and strength. There are occasional attacks of palpitation and tachycardia. Nervousness to the point of insomnia may occur. A tremor is always present. Exophthalmos never occurs. Thrills and bruits are absent. A progressive hypertension occurs. The basal metabolic rate averages thirty-eight per cent.

Treatment in these cases is surgical, providing the damage to the vital organs has not progressed to such an extent as to preclude the probable chances of recovery. Careful examination should be made of the heart and kidneys, and the patient's general

condition should be built up as far as possible by palliative measures. Every case that I have operated upon has been digitalized before operation, although I am aware that considerable difference of opinion exists on the advisability of this procedure.

These cases carry the highest surgical mortality of any goitre operation, the mortality rate ranging from one to ten per cent. Patients who recover invariably gain in weight and strength and greatly improve. The damage that has already occurred cannot be repaired but only checked. If every patient with an adenomatous goitre was operated on before the age of thirty, toxic adenoma could be eliminated from our classification.

Iodine hyperthyroidism.—I have applied this term to the toxic condition that may occur when iodine is administered to an adult having an adenomatous goitre. This toxic state was recognized by Kocher, who warned against the promiscuous use of iodine, because in many ways this condition resembled exophthalmic goitre, or Basedow's disease. Breuer called it iodine Basedow. Consequently, it has generally been confused with exophthalmic goitre and this is largely responsible for the widespread fear of using iodine in exophthalmic goitre.

In a recent series of articles I have endeavored to show that this condition is a distinct clinical entity. It occurs only in patients with adenomatous goitres. The average of the patients in my series of cases was thirty-five years. Tremor, nervousness, loss of weight, tachycardia, loss of strength and insomnia occur as in other forms of hyperthyroidism. The onset of symptoms, however, closely resembles that of exophthalmic goitre because of its short duration, that is, about two months. There is a peculiar characteristic type of nervousness, an extreme restlessness and lack of cooperation that may go on to fatal delirium. There may be a rapid loss of weight, as much as fifty pounds in two months. It does not resemble exophthalmic goitre either in the clinical or pathological pictures. Thrills, bruits, and exophthalmos do not occur. The basal metabolic rate average thirty-one per cent. in a series of fifty cases previously reported.

In the early stages these patients may respond to medical measures and gradually quiet down. In the majority of patients thyroidectomy will be found necessary for relief of symptoms. In this series there were three deaths, one surgical.

Intrathoracic and substernal goitres.—If the major portion of the goitre lies within the thoracic cavity, it is termed an intrathoracic goitre. This type is not common. It gives rise to pressure manifest clinically by cough, dyspnea, cardiac disturbances, dilated veins on the chest wall, etc. The x ray is a valuable aid in diagnosis. Surgical removal may be technically difficult. In order not to compress the trachea it should be freed as far as possible before attempting delivery of the goitre.

Substernal projections of adenomatous goitres are frequently encountered and may be troublesome because of the increased tendency to hemorrhage from tearing of the lateral veins.

Exophthalmic goitre.—This condition should be one of the easiest to diagnose and yet so varied are the clinical manifestations that patients so affected are treated for stomach trouble, heart lesions, hysteria, etc., until the disease is well advanced. It is possible only briefly to review a few points that aid in the diagnosis. The cardinal symptoms of exophthalmos, tremor, tachycardia, nervousness, and goitre have been fully appreciated for over half a century. The fact is not generally known that exophthalmos occurs in only fifty per cent. of the cases within the first three months. A variable and at times excessive appetite accompanied by a steady or rapid weight loss; a characteristic weakness of the quadriceps group of muscles; a high pulse pressure characterized by a low diastolic pressure; the presence of thrills and bruits; and a peculiar type of restlessness observed in no other disease are points that have proved of more value to me than the old time worn cardinal points.

The onset of symptoms in these cases is rapid, averaging months as compared to years in cases of toxic adenoma. The disease occurs more frequently in young persons, the average age being twenty-six.

Contrary to a generally accepted view, fever is present only during a crisis; hence, the oft discussed question of a differential diagnosis from tuberculosis should not be difficult. Exophthalmic goitre progresses by acute exacerbations and periods of remission. At the crests of these waves of hyperthyroidism all symptoms are intensified and gastrointestinal crises occur.

The introduction in 1922 by Plummer of the use of iodine as an aid to the surgical treatment of exophthalmic goitre has completely revolutionized the treatment of this disease. This advancement at once removed the greatest obstacle, hyperthyroidism, from the successful handling of these patients by the surgeon. Within forty-eight hours after receiving iodine, the restlesness, emotional instability and apprehension of these patients begin to disappear. Sleep is restored, the heart slows down.

I began using iodine in these cases early in 1923 and at once appreciated the great benefit to be derived. Although at first I proceeded cautiously, performing one or more ligations, I gradually eliminated the multiple stage operation entirely and have recently completed a series of one hundred primary thyroidectomies for this condition. It should be remembered, however, that the many other factors that go to make up a successful thyroidectomy were most favorable both from the viewpoint of teamwork, anesthesia, confidence of the patient, etc. Unless one has had considerable experience, he should proceed cautiously and slowly in this work and not rely too much on iodine to help him out of a tight situation. Complications, such as tracheitis, hemorrhage, pneumonia, anoxemia and injury to the recurrent laryngeal nerve, may occur at any time.

One of the most striking changes that occurs in these cases after the administration of iodine is the new pathological picture. In the first operation that I performed after using iodine I observed that technically the operation seemed much easier. The gland was not so friable and there was less tendency to hemorrhage. Microscopic study of these specimens revealed the fact that a transitory change had occurred, colloid replacing the areas of hyperplasia. Attention has been called to these studies elsewhere, and also to the fact that while iodine is useful as a preoperative measure it will not effect a cure.

Hepatic Extract

MAURICE F. LAUTMAN, M.D.
Hot Springs, Ark.

Following the announcement by MacDonald (1) that extract of liver contains a substance which is capable of lowering the blood pressure, some further clinical confirmation of the encouraging results obtained by the Canadian investigator might be received with interest. Major (2) reported his general observations on a series of forty-two patients with hypertension and found that the best results were obtained in young persons without evidences of renal damage or arteriosclerosis.

The depressor principle used in the experiments here reported was obtained by subjecting a mash of fresh calves' liver to prolonged extraction with eighty per cent. alcohol. The filtrate was allowed to evaporate slowly. When the alcoholic concentration reached about ninety to ninety-five per cent., the precipitate which formed was collected and dissolved in distilled water. The amount of extract which neutralized the pressor substance contained in one cubic centimetre of a one to one thousand epinephrin solution was used as the unit of dosage.

In all thirty-four cases of hypertension were studied. In twenty-six the age was over forty-eight. Eleven were females and twenty-three were males. Gradual reductions in the systolic pressure ranging from thirty to one hundred millimetres of mercury with corresponding lowering of the diastolic pressure, were noted following courses of treatment varying from ten to twenty-four daily injections. In two cases with pronounced arteriosclerosis no lowering of the blood pressure could be effected.

Patients under treatment were quick to notice the improvement in their feeling of well being, the symptoms which were referable to the hypertension being rather promptly relieved. Vertigo, present in six cases, was benefited. Headaches (six cases), palpitation (four cases), intermittent claudication (one case), and anginoid pains (two cases) were improved. In five cases with evidences of rather marked renal involvement, there was noted a decrease in the albuminuria following the treatment. No untoward reactions or results, either during or after the treatment, were noted, although over seven hundred injections were given. All of the treatments were given hypodermically.

The cases here reported in somewhat greater detail were selected as those which had shown no response to the usually accepted dietary and medicinal treatment for hypertension; in fact, in several there had been a gradual increase in the blood pressure in the face of rigid treatment. The favorable response of these cases to treatment with hepatic extract would tend to confirm the efficacy of this agent.

CASE REPORTS

Case I.—B. H., male, aged fifty-four. Luetic aortitis. Wassermann four plus. Pressures 220-120. After two years' specific treatment the Wassermann test was negative but the pressures were 240-120. Ten daily injections brought pressures down to 140-80.

Case II.—T. H., female, aged twenty-eight. Post scarlatinal nephritis with hypertension. During the past four years, in spite of rigid diet and care, the pressures have increased from 140-80 to 180-110, with the urine showing two per cent. of albumin and many hyaline and granular casts. After seven injections of liver extract the pressures were 130-70. The pressures could not be lowered beyond this figure by seven additional injections although the albumin and casts in the urine appeared to be somewhat further diminished by the additional week's treatment.

Case III.—S. E., female, aged fifty-six. Chronic cardiovascular disease. Pressures 210-110. Daily injections of liver extract for three weeks brought pressures down to 140-85.

Case IV.—C. S., male, aged seventy. Pressures 200-130. Hypertension with beginning myocarditis. Severe attacks of palpitation. Injections of liver extract for twenty days brought pressures down to 150-100.

Case V.—D. C., male, aged sixty-eight. Arteriosclerosis with hypertension. Pressures 200-110. This patient was under treatment for six weeks. After seven injections the pressures were 150-95. The injections were then given twice weekly for five weeks during which time the pressures were never over 150-100.

Case VI.—C. M. R., male, aged fifty-eight. Hypertension with arteriosclerosis. Extremely nervous, irritable and dizzy. Pressures 220-140. Daily injections of liver extract for fourteen days brought pressures down to 145-85. An additional week's treatment produced no further change. There was marked improvement in the nervous symptoms and dizziness.

Case VII.—K. K., male, aged fifty. Simple hypertension with no symptoms. Pressures had been up to 220-130 at one time but were 180-110 when treatments were begun. After fourteen treatments the pressures were 145-85. Treatments were discontinued for one week at the end of which time the pressures were 150-85. After seven more treatments the pressures were 140-80.

CONCLUSIONS

1. Extract of liver contains a principle which is capable of reducing the blood pressure.
2. It exerts a favorable influence on the symptoms which result from increased blood pressure.
3. In thirty-four cases studied, there was a gradual lowering of the systolic blood pressure of from thirty to one hundred millimetres of mercury. Only two cases failed to respond to the treatment.
4. No untoward reactions or results were noted from its use.

The Production of Mydriasis in Rabbits with Thyrotoxic Blood Serum and Adrenaline

ROBERT L. PITFIELD, M.D.

Philadelphia

It is perfectly conceivable that in cases of hyperthyroid disease, either with or without exophthalmos, there is a toxic substance circulating in the blood. That there is an irritant to the involuntary nervous system in persons suffering from this disease is patent to everybody. Long was it considered that this irritant was derived from the thyroid gland (thyroxin). It, however, has been proved by numerous observers that this is not the case. Assuming that a toxic matter does exist in the blood of toxic thyroid cases I applied the serum from such a patient to the eye of a rabbit hoping that I might induce a mydriasis. The sympathetic is more exposed in this organ than anywhere else in the body of a rabbit as in other animals, and it is thus easier to observe it and to experiment on it than elsewhere. No dilatation ensued. Knowing that adrenaline when applied to the eye of an animal in which the sympathetic has been severed, with removal of the ganglia on the same side, produces, according to Landowsky, a mydriasis, this reagent was added to the toxic serum in the eye but produced no dilatation. Toxic matters irritating the sympathetic cause it to become sensitive to adrenaline. Attempts have been made by this method in the eye of frogs to detect toxic matters in body fluids, but without success. If a frog's eye is immersed in Ringer's fluid after being enucleated and adrenaline applied, mydriasis occurs. The sphincter pupillæ, Joseph found in the case of an eye partially or wholly enucleated, will relax if adrenaline even in the dilution of one to one hundred thousand is added.

Thinking perhaps that a stronger and longer contact with the sympathetic nervous system of the toxic serum with the assistance of adrenaline was necessary, one c. c. of the toxic thyroid serum obtained from a woman with marked hyperthyroid symptoms was injected into a rabbit. Shortly afterwards two drops of adrenaline solution (one to one thousand) at regular five minute intervals were instilled. At the end of forty minutes complete paralytic mydriasis occurred. The pupil did not react in the least to the bright light of a small electric bulb (ophthalmoscope) held a few millimetres from the cornea. The pupil of the other eye exhibited lively contractions.

It is best to perform this experiment in a darkened room. A complete reaction demands total mydriasis. The adrenaline should be instilled from the tip of an eye dropper held vertically; the upper lid should be rolled back by the thumb of the left hand, while the fingers encircle the throat of the rabbit.

This reaction does not begin to take place in toxic goitre cases until after the lapse of fifteen minutes after the subcutaneous injection of the serum; the latter should be kept in a cool place until used. In the short series of which will be given in detail in this communication the reaction took place after varying intervals of time and after varying amounts of adrenaline were instilled. The more toxic cases requiring fewer drops and the reaction became complete in a shorter time. The most toxic serum responded in forty minutes and required but a few drops of adrenaline as an adjuvant. A few controls were employed; many more are required to confirm the rather few findings of this investigation. One was a vigorous young man and the others with irrelevant diseases that were obviously nontoxic thyroid disease. No reaction was obtained by such sera. According to Loewi adrenaline occasionally induces mydriasis in persons ill with Graves's disease. This has been thought to be due to adrenalinemia. With this in view I injected into one rabbit .25 c. c. adrenaline solution (one to one thousand) and copiously instilled this same reagent into its eye without obtaining mydriasis. Stewart, employing strips of intestine and isolated uterus from a rabbit, was unable to detect any evidence of the presence of epinephrin in the blood of persons suffering with Graves's disease (1). Mydriasis may be produced in experimental hyperthyroidism (Falta, Eppinger, Rüdinger). I found (after devising the experiment described in this paper) that Kraus and Friedenthal noted that the blood of toxic thyroid cases produced mydriasis (sometimes) (Falta). But it is not related by what means or how, nor was adrenaline used as an adjuvant. Most of the cases of toxic thyroid disease coming under my observation have slightly dilated pupils from sympathetic irritation; in many other functional diseases of the nervous system this phenomena is, of course, common knowledge.

Recently Hyman and Kessel (2) declared in their article on Exophthalmic Goitre and the Involuntary Nervous System that "the involuntary nervous system may produce manifestations of exophthalmic goitre through the intervention of some unknown circulating sympathomimetic substance, . . . thus far attempts to demonstrate such substance in the blood circulating fluids have proved futile." Plummer, in discussing this paper, says, "Our present hypothesis attributes the latter (the phenomena that characterize exophthalmic goitre) to the action of a toxin, largely on the nervous system. This toxin may be an abnormal thyroid product or the reaction of abnormal thyroids on the tissues of the body."

The following cases are reported with detailed accounts of the experimental mydriasis or nonmydriasis, depending upon the properties of the blood serum employed.

Control: serum from Mrs. Sch., a married woman, aged forty-seven, neurasthenic, suffering much from depression and apprehensiveness, with no signs of hyperthyroidism or other thyroidal trouble, was injected into a healthy young rabbit. At each of the following times two drops of adrenaline were instilled into the right eye: At 10:09, 10:11, 10:16, 10:21, 10:26, 10:31, 10:36, 10:41, 10:46, 10:51 eye proptosed pupil slightly larger than left; 10:56, 11:1,

11:11 nictitating membrane retracted; 11:16, 11:21, 11:26.

Thirty-three drops or one c. c. adrenaline were instilled in right eye. Both pupils reacted to light; right was larger by about one millimetre, but there was no paralytic mydriasis; pupil in right eye was not immobile. Time seventy-seven minutes. This rabbit responded to the toxic effects of adrenaline by proptosis of the eyeball and a mild but not fixed dilatation of the pupil.

Control: serum from a woman aged sixty-one with indefinite symptoms of spinal sclerosis and no indications of any thyroidal disease.

At 10:02 one and a half c. c. serum injected into rabbit; at 10:07 two drops adrenaline one to one thousand instilled in right eye; 10:12, 10:17, 10:22, 10:27, 10:32, 10:37, 10:42, 10:47, 10:52, 10:57, 11:04 two drops adrenaline; 11:09, 11:14 three drops adrenaline instilled. At the end of sixty-seven minutes there was no mydriasis nor proptosis of the eyeball. After one c. c. of adrenaline the experimented pupil was very slightly larger than the untreated, but very mobile. The nictitating membrane was slightly retracted and looked paler and thicker than the one in the other eye.

Case I.—Mrs. P., aged forty-one, a nervous, unstable woman, given to weeping and other evidences of emotional imbalance, exhibited a large adenomatous thyroid. Her family history is important to the extent that her sister also had thyroid disease and died during an operation for its relief. Her own history is that of a married woman harrassed by the cames of a family, and with a poor nervous equipment. Toxic tonsils had been removed. Both lobes of her thyroid were the seat of neoplastic growth. She exhibited every symptom of toxic thyroid disease except the protrusion of the eyes and the usual concomitant signs of exophthalmos. She had a weak rapid heart with a pulse rate ranging over 140; in addition she had tremor of the tongue and hands but no mental symptoms; was apprehensive to a marked degree.

Three quarters c. c. of this woman's blood serum was injected under the skin of a rabbit and adrenaline in small drops slowly instilled into one eye of the animal. At the end of fifty minutes after the use of six drops (.20 c. c.) adrenaline one to one thousand, complete mydriasis occurred; the other eye exhibited lively contractions. The pupil of the experimented eye was so large that but a small rim of the iris could be seen. If larger amounts of adrenaline had been used at more frequent intervals it is likely that a prompter reaction would have appeared. After the lapse of two hours and seventeen minutes mydriasis was still present. This woman had a very toxic goitre. Since then a subtotal thyroidectomy was performed with recovery of the patient.

Case II.—Mrs. M—y, a middleaged woman, had a partial thyroidectomy done seven years previously and exhibited every sign of toxic goitre when seen, except the eye symptoms, having mental depression, anxiety neurosis, tremor of the hands and tongue. Her heart was weak and pulse rapid. Dr. Langdon, in whose practice this woman was, told me that all of her thyroidal symptoms had been precipitated by the sudden death of her child. After the injection of one c. c. of serum the instillation of twenty-eight drops (.85 c. c.) of adrenaline, mydriasis was complete in seventy-seven minutes. This case is not as toxic as the first one.

Case IV.—Mrs. P—t, a young Italian woman, aged twenty, married but without children, was seen with Dr. Langdon. She exhibited every sign of toxic thyroid disease, enlarged gland, tremulous hands, moist skin, rapid pulse 136, basal metabolism of plus 53, mental symptoms appeared now and then after fatigue.

One half c. c. of her serum was injected into a rabbit and seven drops of adrenaline instilled drop at a time at regular intervals for forty-two minutes; at the end of this period no mydriasis appeared. Then one half c. c. more serum was injected and in ten minutes two more drops of adrenaline were instilled. Mydriasis was complete after the lapse of sixty-nine minutes, with the use of nine drops (.27 c. c.). The dilatation had disappeared in 169 minutes.

Case V.—This case has been reported for the reason that notwithstanding it was one of marked toxicity no reaction was obtained, either because I did not use sufficient adrenaline, or because the patient had been under active medical treatment, ingesting large amounts of iodine and quinine daily, with great improvement in her condition.

Mrs. W., the patient, aged fifty-three years, had suffered for one year from toxic thyroid disease, which had supervened after a carbuncle on her neck had been cured. When first examined she had a fibrillating heart, which was decompensated and dilated, her legs were edematous and the cardiac impulse weak. She had a marked tremor, pulse of 130, even while under rest and digitalis. A Dalrymple sign appeared after she had been ill six months. Her basal metabolic rate was plus 17 and plus 34 on different occasions.

One c. c. of her serum was injected and eighteen drops (.56 c. c.) adrenaline instilled at regular intervals for seventy minutes at this time there was no mydriasis. This may have been prevented by the use of the drugs or insufficient adrenaline instilled as I have suggested.

Case VI.—Mrs. F., a tall gaunt woman very thin and neurasthenic and asthenic in every way, exhibited every sign of toxic thyroid disease two years ago. Then her pulse was very rapid, 140, her basal metabolism ranged from 38 to 80 plus. Under rest and digitalis this subsided to plus 15. Her thyroid was never enlarged nor were there any eye symptoms. An old subacute tuberculous lesion was evident in her right lung. In 1924 Dr. Frazer did a bipolar ligation of her thyroid arteries under gas anesthesia.

Her weight at this time was but eighty pounds, her height being five feet seven; she was but a skeleton. From this operation she slowly convalesced. Eighteen months later her weight had risen to 123. Her tremor had disappeared, her heart was strong enough for her to work all day as a dressmaker. Her pulse rate was eighty on several occasions in spite of excitement and at the end of a tiresome day. Symptomatically she is well, exhibiting no signs of toxic goitre in any way and being able to support herself.

One and a half c. c. of her serum was injected into a rabbit and two drops of adrenaline were instilled into its eye at regular intervals; after using twenty-eight drops (.85 c. c.) of this reagent and waiting

for 120 minutes there was no mydriasis. It can be inferred from this experiment and her examination that this woman now has no signs of toxic thyroid disease.

Case VII.—H., a child of eight, with a large adenomatous growth in her thyroid, was examined. She had no nervous or eye signs of hyperthyroidism, her weight was normal so was her pulse and heart. Thinking that an estimation of her basal metabolism would be of service in her case she was referred to the University Hospital; there this estimation proved to be normal. In fact there could hardly be a doubt as to the benign character of her thyroid enlargement. Six months later three quarters c. c. of her serum was injected into a rabbit, and adrenaline instilled, after the use of twelve drops of this reagent and after the lapse of 120 minutes, there being no mydriasis, it was concluded from this rather incomplete study and taking her clinical symptoms into consideration, that this thyroid was not in the least toxic and the reaction negative.

Case VIII.—Mr. W. W., a large strong, nonnervous man in excellent health, exhibited a large adenoma in the right lobe of his thyroid. He exhibited no signs of toxic thyroid disease, his pulse was 64, his heart strong and normal in every way, there were no eye or nervous symptoms. His blood pressure was 100-76, his urine normal.

One c. c. of his serum was injected into a rabbit and adrenaline instilled every five minutes into the animal's eye. In all twenty-four drops (.72 c. c.) were instilled. After the lapse of eighty-five minutes the pupil was sluggish. At the end of 120 minutes, an hour after the instillation of the last adrenaline, there was a fixation of the pupil in moderate dilatation; it did not respond in the least to a bright light, held for two minutes very near the cornea.

Case IX.—Mrs. D., aged fifty-one, referred by Dr. Harry Webber for examination and diagnosis. Her chief complaints were weak heart, swollen legs, loss of weight and neuralgic pains in her arms and back. She was at her menopause, the last menstruation having occurred about four months before her examination. Previously her menses had been regular and symptomless. Her past history was unimportant; she was the mother of three children and had the usual diseases of childhood, including scarlet fever; she also had suffered from tonsillitis as a young woman. Recently she had lost twelve pounds, looked anemic and below par. Her heart bothered her when she exercised, and she became dyspneic and weak. Her thyroid was obviously much enlarged. Her pulse was rapid, 140, weak, but regular. Her cardiac dullness seemed normal, impulse feeble, no murmurs near the apex but at the pulmonic area a socalled vasomotor murmur was heard. Her legs were edematous. The right apex of the lung was the seat of an old tuberculous process, now dry and symptomless. There were no toxic thyroid symptoms of her eyes, her forehead did not wrinkle on looking upward, the pupils were moderately dilated. On extending her fingers a fine tremor could be seen.

There was no tremor of the tongue. She had an anxiety neurosis and other mental symptoms. Her hands were moist and clammy. The diagnosis lay between a toxic thyroid with enlargement and neurasthenia with a weak heart. The thyroid was enlarged to the size of half a small orange in the isthmus, an adenomatous mass could be palpated. Except for her weak heart, enlarged thyroid and nonwrinkling forehead, all her symptoms might be classed as neurasthenic. Being at the menopause and having an adenomatous growth in the thyroid which might be nontoxic in character, and an old lesion in her lung, a diagnosis of secondary neurasthenia might be justified. No opportunity to make a metabolic rate estimation was at hand.

One c. c. of her serum was injected into a rabbit, two minutes after adrenaline instillations were begun, and continued every five minutes. At the end of twenty-two minutes and after the use of ten drops (.30 c. c.) adrenaline solution one to one thousand, complete mydriasis occurred. Dilatation of the pupil had disappeared in sixty minutes. The reaction, if it proves to be a specific one, means that this woman has a toxic thyroid and not a pure neurasthenia.

Subsequently a subtotal thyroidectomy was performed. She recovered slowly but completely. Her metabolism at the hospital was found to be plus 41.

One half c. c. serum of this woman's blood was heated to 58° C. for 140 minutes and then when cool it was injected into a rabbit. Mydriasis occurred after the lapse of twenty-eight minutes and the use of twenty-four drops or .72 c. c. adrenaline. From this solitary experiment with heated serum I infer that the toxic substance, if there is such a real entity, is thermostabile.

It is obvious that patients should not take belladonna or other mydriatic before the blood is drawn.

From experiments not related in this paper I am led to the conclusion that iodine in some way inhibits this reaction, perhaps by neutralizing the hypothetical substance.

If a conclusion can be drawn from these preliminary experiments with the sera from toxic and nontoxic thyroid cases, the following requirements then should be postulated:

1. One cubic centimetre of the suspected serum should be injected into a healthy rabbit.

2. The reaction cannot be considered to be negative unless one cubic centimetre of adrenaline solution, one to one thousand, has been instilled into one eye of the rabbit.

3. Complete mydriasis should appear within ninety minutes' time.

4. The quicker the reaction appears and the fewer the drops of adrenaline used, the more toxic the case and the more certain the reaction is.

It is quite possible that by the use of two c. c. of serum, instead of one, prompter and more definite results may be obtained.

SUMMARY OF EXPERIMENTS

I.	Cases in which there was no reaction:		
	Those without thyroid symptoms of any kind..	2	
	Those with nontoxic enlargements of the gland	2	
	Those with supposedly cured or arrested hyperthyroidism	2	6
II.	Cases in which there was a reaction:		
	Hyperthyroidism	5	5
	Total		11

5211 Wayne Avenue.

Other cases cited by the author have been omitted for lack of space. They will be included in the reprints.

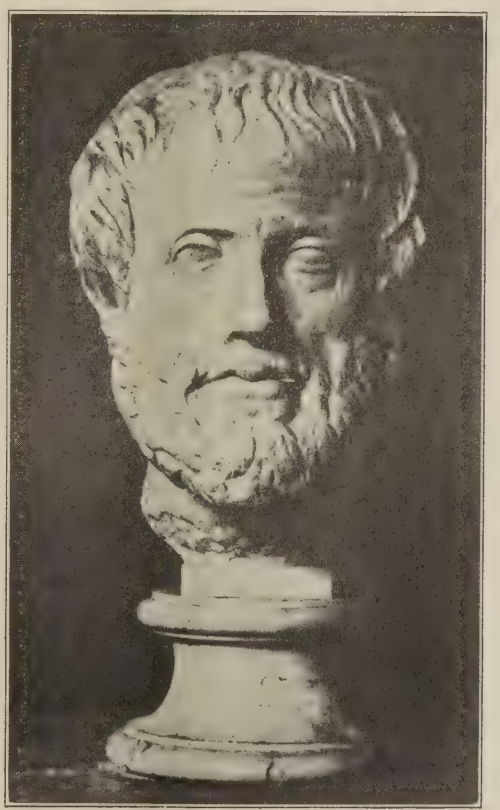
Historical Medicine

The Legacy of Greece to Galen

1. The Elements of Matter

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

When we stop to consider that Galen was born nearly six hundred years after Hippocrates and that for nearly half that time there were no efficient methods of diffusing knowledge and only then by the public libraries at Pergamum and Alexandria; when we remember that Hippocrates was alive when Plato wrote, possibly when Aristotle was born; when, having these things in mind, we perceive how Galen on page after page of his interminable writings is quoting and referring to them, we get some inkling of the vigor of Greek thought in the fifth and fourth centuries B. C. This is impressed upon us quite independently of the realization of how much we owe to the legacy of Greece ourselves, how much we still live in its light. To us that epoch and that land is far away and misty and it is with an effort to fix our attention on the thought that sprang into life there and then. To Galen they were the breath of his intellectual life and the names that were associated with the lands he himself had traveled over and dwelt in were ever at his pen's point.



ARISTOTLE (Vienna)
(After Hekler)

In the first volume of Kühn's edition of his works there is a book on the *Elements of Hippocrates* (1a). Many a student of Hippocrates will have read his works without perceiving Hippocrates ever said anything about the elements of matter, unless he reads the spurious book, which Galen believes genuine, on *The Nature of Man*. For Galen it was the chief of the works of Hippocrates. From it he drew his inspiration for the humoral doctrine which fettered the thought of medicine for sixteen hundred years. We have good reason to believe this book was not written by Hippocrates II, but by some younger member of his family, very likely in the time of Aristotle, who definitely attributes the part on the anatomy of the veins to Polybus, his son in law. A modern critic remarks (2) that Galen had no real reason for thinking Hippocrates the author except his admiration for the doctrines set forth in it and I can not help thinking his admiration carried him so far occasionally as to put thoughts in his mouth he never thought, just as Plato laid things in the mouth of Socrates which Socrates is declared to have said he never had in his mind. Even Galen admits the parts after chapter X are spurious and the work neither of Polybus nor Hippocrates but of some Alexandrian. However, whoever was the author of the first nine chapters displays in them a mentality which we believe is so far below that of what are regarded by all critics as genuine, he could not have been the one who wrote the latter. Plato put words in the mouth of Socrates which the latter had no cause to be ashamed of, and if Hippocrates had come to life again after six hundred years he would have had a juster cause for complaint against Galen. Even if he thereupon confessed he was the author of *The Nature of Man* he might have denied some of it in Galen's version and that he twisted other things to absurd conclusions. As we go along we shall have occasion at least to intimate this.

We find Galen at the beginning of his commentary pointing out that Hippocrates was well aware the particles of the elements are smaller than the senses can appreciate. Democritus is said to have been born in the same year (460 B. C.) as Hippocrates. They are said to have corresponded and Hippocrates is said to have paid him a professional visit. The latter assertions rest on manifestly forged evidence, but even so we need not conclude that Hippocrates had this doctrine from Democritus. The extension *The Nature of Man* gives to the ancient atomic theory is not the product of one generation. It has every appearance of having evolved at a date later than the fifth century. The solid particles of the element earth when reduced to the finest powder all feel alike, but they are not alike and the same is true of other forms of the other elements. The author of *Ancient Medicine* or of *The Epidemics* I and III is not apt to have written that. Even if the derivation of monism from Melissus in the time of Hippocrates and Pericles is indicated by the mention of his name in *The Nature of Man* it is not a proof that Hippocrates wrote the latter. It is rather suggestive of some one in the time of Aristotle familiar with that particularly vulnerable form of monism gives it a slap

because greater men had shown it was indefensible.

Melissus it was who declared the "one" unchanging and infinite and this sprang from the opinions of the nature philosophers before him, some of whom had made one or the other of the four elements the ground form of the universe, but susceptible of change into the forms of the others. Melissus had it unchanging. Galen thinks if we must have this unity, it had best be unchanging and he alludes to Hippocrates casting a doubt upon the whole doctrine by remarking each philosopher had a different element as his base. Aristotle, too, he says shows up this foolishness in his work on the nature of hearing. I am at a loss to know if this is the *De Audibilibus* which the most recent translators (Oxford) of Aristotle think is spurious—probably by Strato. It is poor stuff at any rate, but I see nothing in it to bear Galen's statement out. The unchanging form of being, the Unmoved Mover of Aristotle, is purely metaphysical and it is just as hard to derive from Him naturally any one or more of the elements as it is from the conception of Melissus. However that may be, both Plato and Aristotle in their works virtually accept the monism of the ancient philosophy. Indeed Plato describes it and it is the essence of Aristotle's *Coming to Be and Passing Away*. It is in the little work on *Melissus*, usually edited with Aristotle's genuine works, that the theory of the unchanging nature of matter is attacked, but Diels and modern critics (3) think this work was written as late as the first century A. D. We may conjecture Galen was here speaking (1b) from memory and it misled him or that Aristotle was regarded by him not only as author of the work on hearing, but also of the one on Melissus. This does not seem likely if the book was of a date so near the birth of Galen. The treatise on Melissus is one of considerable merit and I do not see, as far as that goes, why Aristotle might not have written it and it is in the first chapter of this brochure and not in the first chapter of that on hearing that the doctrine of Melissus is shown, as Galen thinks, to be absurd.

After claiming Aristotle quite supports his view Galen goes on to say in the spirit if not in the words of *The Nature of Man* that if there is only one element and that common to all substance it would destroy the art of medicine, for there would be but one disease and one cure. In fact it not only destroys art but man himself. Aristotle and Hippocrates he thinks are in agreement on this point, but I don't believe the real Hippocrates ever thought that and I fail to remember that Aristotle in his genuine works draws such far reaching conclusions. As to such simplicity as one drug, any one glancing over the Galen pharmacology can see from its shotgun nature that it would be very difficult for him to cut himself down to one drug. Some of them are marvels in the way of multiplicity. Even with four elements they would seem to Galen very much less tractable to change than the ninety odd do to us, or, however many there may be when this commentary finds its way into print, but then no more than now, with four no more than ninety-four was it easy to find them unadulterated. "They exist unmixed in thy body no more than in that of any other animal"—and he makes sport of it. Fire is of the nature of air, but especially of the pneuma, and penetrates everywhere.

Athenaeus, the Attalian (of Pergamum?) reckons the qualities themselves as elements, the dry and the moist, the hot and the cold. They, too, were according to him elementary parts of the human body, "ridiculed with censure now by many and laughter not a little." It was criticized in the ancient arguments, but it is the natural tendency in an age when the corporeal was not yet clearly distinguished from the incorporeal, for that is the thought all ethnologists relate of primitive men. Indeed why should Galen jeer? Why should we? Is not heat motion? Is not motion energy? Is not energy merged with matter in the hottest stars according to the latest bulletin from them? Herr Mie (4), whom I have quoted elsewhere, only last year suggested there is no reason why matter should not disappear like the Cheshire cat and leave only the smile behind. But what else could Galen make out of Plato's Ideas as realities? Man and all that surrounds him are but shadows of realities. They may vanish and leave behind beauty, truth and justice, why not the hot and the cold, the moist and the dry? Monism indeed leads us into strange lands today, but they ought to have been more familiar to Galen. When he says (1c) and makes Hippocrates say if there were only one substance man would have no feeling, for us indeed he dwells in strange lands, for us whom Spencer has taught how out of the homogeneous the heterogeneous is born, but why is the surviving smile of the Cheshire cat ludicrously strange for us. Galen simply taps the reservoir of ancient argument, but we have no resource against the modern monistic physicist and astronomer. This ancient argument Plato and Aristotle developed, but I am not aware that they did so anywhere in the way Galen attributes to Hippocrates.

However, after all it may be essentially the same. Unless there is something opposite to it there can be no sensation. We must know the bitter to recognize the sweet. That is doctrine older than Plato. It takes two things at least to form the substance of matter we can recognize by the senses. The heterogeneous we might say begins to merge early from the homogeneous, but it is more in accord with ancient argument to say there must be the knowing thing as well as the thing known. Aristotle says there can be no image of an image. We may agree there seems no escape thus for the ancient and the modern. For the ancient, for Hippocrates, as interpreted by Galen, if there is a wet there must be a dry, if there is a hot there must be a cold. It is true the modern materialist sees at once, but it perhaps was not so clear to a world more steeped in mysticism than ours, that the analogy does not hold. I am not at all sure that Plato or Aristotle carries the argument thus astray, and if they did not, I am quite sure that Hippocrates did not, but Galen and the author of the book *On the Nature of Man* wear these sophisms threadbare.

He sets forth the doctrine of Democritus that the bitter and the sweet are conventional terms and that matter has no attributes, the true atom has neither heat nor cold. Essentially this is the basis of the doctrine of Protagoras. For men the words black and white have a meaning, but they have no application to elementary normal substance, neither the bitter nor the sweet, not the hot nor the cold. So far

as these are concerned the atom is a vacuum. By a vacuum, however, the ancient meant space, the void, where the elements are borne up and down and round about through all eternity and woven together with one another and strike against one another and rebound from one another. Time and space, however, did not exist for Aristotle aside from matter any more than it does for the modern physicist, but for others, as for Galen, it was something that separates and unites the atoms. Lodge and the etherists, Einstein and the relativists, had their prototypes before Galen and perhaps Hippocrates belongs among the dualists, but outside of *The Nature of Man* we get no intimation of it and it is the belief of most critics that Galen made him responsible for that which he at least had not thought out.

It is very probable that in the later life of Aristotle the scientific thought of Greece had analyzed the arguments and had reached the development views of this kind had initiated, but much of this in the way of confirmation or denial lay in the germ in the time of Hippocrates, just as much of the thought in today's physics was still in the germ before Sir Joseph Thomson split the atom. On comparing *The Nature of Man,* as it exists in the Hippocratic Corpus today, with this commentary of Galen on it, we not only take note that he has apparently committed an anachronism, but he has gone beyond the development of the matter as it exists in the text we have of the Hippocratic work. Epicurus may have visualized matter stripped of attributes or may have thought he did in Aristotle's *Unmoved Mover* but not of such matter this side of metaphysics. The *Timæus* of Plato makes even the mystical Receptacle impressible and these are doctrines later than Hippocrates unless we get a line on them in those ascribed to Protagoras by the Platonic Socrates. Galen emphasizes the view he ascribes to Hippocrates that if matter were all one there would be no opposite sensibles for the senses to work upon. This form of the argument seems to be the later consequence rather than the basis of the views either of Democritus or Protagoras, but we find Galen thus up to his neck in the Greek thought of an era half a millenium behind him and it behooves one with five times that space of time behind him to be much less sure he has grasped it. Others have, far better than I can hope to do, discussed the authenticity of the books of Hippocrates. Truth, they say, is stranger than fiction. History is, anyhow, and there is often—usually you may say in one sense which I will not stop to develop here—more truth in fiction than in history, so why disturb the smug conviction that Hippocrates never wrote nonsense, and that Socrates was the wisest and best and most lovable of men? Ideals, at least sometimes, are worth more than the truth.

It is doubtless true that the absurdity of supposing man's senses were coeval with the birth of matter was not so apparent in the days of Hippocrates or even in those of Galen as today. The doctrine of evolution may not be all true or all the truth, but it has helped the thought of man on its way to getting a better grasp on the truth. What can you say better of a theory? The doctrine of evolution and the revelations of physics in modern days have convinced reasonable men that the unfolding of the universe to man has been keeping step with the evolution of the sense organs and the deepening of the cerebral sulci. Even as early as Hippocrates he could be expected, as Galen needlessly declares, to distinguish between a man and a stone, because man feels and inanimate material does not. If he were made of one element he would not feel, but why should a mystic mention that it requires a mixture of the elements thus to insure consciousness? Whether that or its archetype in ancient science, the soul, is associated with one element or a dozen, it remains a mystery still. But Galen goes on to say the atoms of flesh must have sensible attributes, otherwise man would not feel when a needle's point touches only one atom. I have not looked it up, but I don't think Hippocrates ever said anything like that. For a moment it confuses our minds, we are lost not so much by the vacillation of the argument as by the realization that an atom for Galen does not seem to be indivisible and at any rate is not our atom at all. An atom had for him here an attribute he could understand by an appeal to sense and manifestly from his previous argument an atom must be made up of two or more elements. I am not going to shout across the ages at Galen as he does at Chrysippus or apostrophise him as he does Asclepiades and Erasistratus, but bewildered take note that for him sensation seems to be an alteration in the state of matter. At least this leaves us undismayed.

We get an echo of the mysticism of Aristotle, unacknowledged by Galen, in the assertion (1d) that "although there may be sensibility in capacity, in energy there may not be at all." Actually we may not hear but the capacity for it may exist. Aristotle meant something more than that, he meant attributes of matter may exist independent of man's sense of them. He is by no means always consistent in this, but as I remember he seemed to think sound would exist even if there were no ears. One hesitates to impute anything so puerile in thought to Galen, much less to Aristotle, but Galen seems to confuse capacity with man's having an organ of hearing and Aristotle seems to confound sound with the impact of shocks of matter on the air. As I have intimated others have written more wisely on Aristotle and Galen than I, at least more confidently. It seems clear, however, that Galen believed that the elements of matter each one by itself have no attributes, but the mixture of them does and he ascribes this view of them to Hippocrates. Notwithstanding his bewildering remark about a pin's point and the atom further on in his essay he thinks not only do the atoms have no sensibility, but they have no memory or recollection, no imagination, for sensibility is at the root of these. If none of these then it has none of the other attributes. An atom has no soul, but a collection of them does. We had an echo of Aristotle at the beginning of this paragraph and I end it with this echo from the *Timæus* of Plato. In the fabrication of the soul in the Receptacle God or his demiurge mixes the elements of matter with the divine.

Then we return to Galen's objection, which he says was also that of Hippocrates, we grasp easily enough the difficulties. In order for feeling to exist there must be something felt. These are two at least. There can be no image of an image, Aristotle objected to Plato. Matter must be multiple. Thus we find the horns of a dilemma from which there is

no escape in monism. In all ages of philosophical thought they have existed. All evidence points to monism. All reason rejects it.

Contributors to the Science of Medicine

William Hunter

William Hunter, an elder brother of John Hunter, is somewhat overshadowed by the fame of his younger brother, but the claims of William Hunter to live in the memory as a great contributor to medical science are unassailable. His brother was more original and may be regarded as the greatest pathologist and one of the greatest comparative anatomists of perhaps all time. William Hunter was also a very great anatomist and did much to revolutionize the study of the subject to add to the knowledge of anatomy and place it on a solid basis.

As Dr. Peachey in his remarkably able memoir of William and John Hunter says, "In his examination of Scottish intellect during the eighteenth century, Buckle, the historian of civilization, after reviewing the philosophical works of Francis Hutcheson, Adam Smith, David Hume and Thomas Reid, and the scientific labors of Joseph Black in chemistry, of James Hutton in geology, of James Watt in mechanics, and of William Cullen in medicine, sums up by saying: 'I have now only one more name to add to this splendid catalogue of the great Scotsmen of the eighteenth century; but it is the name of a man who for comprehensive and original genius comes immediately after Adam Smith, and must be placed far above any other philosopher whom Scotland has produced; I mean of course John Hunter.' "

Dr. Peachey further points out that among men of outstanding ability selected by Francis Galton to illustrate his theory of the transmission of hereditary ability may be found in the first degree the name of John Hunter, and on a lower plane the names of his brother, William, his nephew, Matthew Baillie the pathologist, and his niece, Joanna Baillie the poetess. Galton also found that most of his selected men of science were nurtured by able mothers, and we know that Mrs. Hunter was a "woman of great worth and considerable talents."

In connection with medical and surgical science and progress it may be pointed out that the Scotch have been always foremost, perhaps, especially so in anatomy and surgery.

William Hunter was born on May 28, 1715, at Kilbride, in the county of Lanark. He was the seventh of a family of ten children whose parents, John and Agnes Hunter, resided on a small estate in the parish named Long Calderwood. At the age of thirteen years he was sent to the University of Glasgow where he passed five years, distinguishing himself as a good and diligent scholar. His father desired him to enter the church but the liberal views that he had imbibed at the university gave him an aversion for theology. It is stated that five years' study of theology produced upon his mind an insuperable distaste for the ministry.

At this time he chanced to become acquainted with Dr. Cullen, the well known Edinburgh professor, and this determined him to enter the medical profession. Late in 1736 or early in 1737 he went to reside with Dr. Cullen who had then left Edinburgh and was established in practice in Hamilton near Glasgow. He remained for three years in Hamilton when he went to Edinburgh for the winter session of 1740. Reachey says at the end of 1739. In the summer or autumn of 1741 he arrived in London and at first lived at the house of Dr. Smellie, an apothecary in Pall Mall.

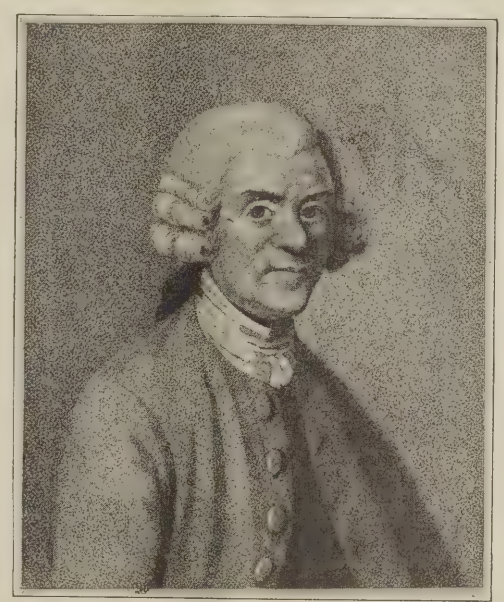
Hunter had brought with him a letter of introduction to a fellow Scot, Dr. James Douglas, who was then intent on a work on osteology and was looking out for a young man as a dissector. He invited Mr. Hunter to become a member of his family, to assist in his dissections and to assist in the education of his son. Having accepted this offer, by the influence of Dr. Douglas he was enabled to enter as a surgeon's pupil at St. George's Hospital under Mr. James Wilkie and as dissecting pupil under Dr. Frank Nichols, who had a considerable reputation as a teacher of anatomy. Peachey says that there is no record of William Hunter having been an apprentice at St. George's Hospital but there is no doubt that he was a pupil there. He soon became an expert dissector. Dr. Douglas died on April 2, 1742, but Hunter continued to live with the doctor's family although, as Peachey says, his doings during the remainder of 1742, after the death of Dr. Douglas, and until the autumn of 1743, cannot be traced in detail, and according to Peachey in September, 1743, Hunter went to France with young Douglas.

In 1743 he communicated to the Royal Society an Essay on the Structure and Diseases of Articulating Cartilages. His object at this period of his career was to teach anatomy and he prepared himself thoroughly with this end in view. He spent several years in acquiring knowledge of the subject and in collecting anatomical specimens. At this time a society of navy surgeons had a house in Covent Garden where they engaged a Mr. Sharp to give a course of lectures on surgical operations. Mr. Sharp, finding that this work interfered too greatly with his practice, resigned in favor of Hunter, who gave so much

satisfaction that he was requested to extend the course to embrace anatomy.

He was remarkably successful as a lecturer. In 1747 he was admitted a member of the Corporation of Surgeons and in the spring of the following year set out in company with his pupil, Mr. James Douglas, on a tour through Holland to Paris. He continued his winter course of lectures on his return. At first he practised both surgery and midwifery but later specialized in midwifery. He was elected one of the surgeon man-midwives, as they were termed, first to the Middlesex Hospital and soon after to a similar post in the British Lying-in Hospital. It was not long before Hunter had established his reputation as the first authority on midwifery in London. In 1750 he gave up surgery, obtained the degree of M.D. from the University of Glasgow, and began to practise as a physician.

In 1755, on the resignation of Dr. Layard, a physician of the British Lying-in Hospital, the governors of that institution voted their "thanks to Dr. Hunter for the services he had done the hospital, and for his continuing in it as one of the physicians." In the following year he was admitted a licentiate of the Royal College of Physicians, and soon after was elected a member of the Medical Society. Peachey says that William Hunter became a member of the Society of Physicians in 1754. His *History of an Aneurysm of the Aorta* appears in the first volume of the society's *Observations and Inquiries,* published in 1757. In 1762 he was appointed physician extraordinary to the Queen.



WILLIAM HUNTER

In April, 1767, Dr. Hunter was made a Fellow of the Royal Society and in the following year communicated to that learned body *Observations on the Bones,* commonly supposed to be elephant's bones which have been found near the River Ohio in America. This, however, was not the only subject of natural history on which he used his pen, as in a subsequent volume he is found offering *Remarks on Some Bones Discovered at the Rock of Gibraltar.* In 1768 Dr. Hunter became F.S.A. and in the same year, at the institution of a Royal Academy of Arts, he was appointed to the post of professor of anatomy. In January, 1781, he was elected unanimously to succeed Dr. John Fothergill, as president of the Society of Physicians of London. He had now a world wide reputation. In 1780 the Royal Medical Society of Paris elected him one of their foreign associates and in 1782 he received a similar mark of distinction from the Royal Academy of Science in that city. His great literary scientific effort was published in 1774 *The Anatomy of the Gravid Uterus.* He also communicated to the Royal Society an essay on *One of the Origins of the Venereal Diseases.*

In 1770 he erected a large house in Great Windmill Street. In this building in addition to a spacious amphitheatre, and other rooms for his lectures and dissections, there was one very large room used as a museum in which was placed his very large anatomical collection. Before he removed to Windmill Street he had confined himself chiefly to collecting specimens of human and comparative anatomy but afterwards his views became more catholic and he gathered fossils, books, coins, shells and various other specimens of natural history. On March 30, 1783, he died from gout from which he had suffered for several years.

The demonstration of the lacrimal ducts in man was achieved by William Hunter in 1747. The demonstration of the tubuli seminiferi was completed by William and John Hunter in November, 1752, and by Monro in Edinburgh in January, 1758. The demonstration of the condition known as congenital hernia was carried out by the Hunters in 1756, acting on a suggestion made by Haller in the previous year.

After publishing his *Treatise of Ruptures* in the following June, Pott, one of the great surgeons of the day, of Pott's fracture fame, called that winter and examined the preparations at the dissecting rooms in Covent Garden which were explained to him by John Hunter himself. Yet in March, 1757, when Pott published a monograph on the subject, he did not mention the Hunters on the preparations he had seen. The discovery of the absorbent system was much more important. Indeed Peachey states, that after Harvey's discovery of the circulation, it ranks as the greatest achievement in physiology in all time.

In his first course of lectures, in 1746, William Hunter explained his views that the lymphatics were not continuations of the arteries, as was then held, but that they were absorbent vessels, commencing in all the external and internal surfaces of the body. In 1752-3 Alexander Monro, Jr., had been able to confirm by experiments what William Hunter had been teaching for six winters, and in October, 1755, he published a short abstract of them in his Edinburgh thesis, *De testibus et semine in variis animalibus.* He then came to London in November, attended William Hunter's lectures, and went on to Berlin, where, early in 1757, he published *De venis lymphaticis valvulosis,* without mentioning William Hunter, though referring to every other writer on the subject. On his return journey he called at Hunter's house in Jermyn Street when, as William asserted, "I was reading my lecture at Covent Garden, that is when he was certain I was not at home." The *Critical Review* for November, 1757, edited by the immortal Dr. Smollet, one of the founders of modern fiction, claiming the right to give an impartial opinion upon the facts submitted by each of the disputants, pronounced judgment in favor of Hunter, a judg-

ment which has been endorsed by the consensus of medical opinion.

Of course, in keeping with the customs of the day a wordy warfare which was waged was coarse and pungent in the extreme. On both sides personalities and invective of the stable yard variety were indulged in. However, it must be borne in mind that in those days a spade was called a spade generally with a strong qualifying adjective. Even Smollet, one of the literary geniuses of all time, was a master of coarse invective so that it can be scarcely a matter for surprise that William Hunter belabored those who tried to filch his discoveries with vulgar abuse. It may be remarked that it was these same Monros who on two other occasions laid claim to priority of discoveries made by the Hunters. Donald Monro, who was a physician at St. George's Hospital, laid claim to priority for his brother on the lame excuse that publication and not demonstration gave one the right to a discovery. However, the general opinion was then and is now that to William Hunter belongs the honor and fame of discovering the object of the absorbent system. This discovery gives him a place among the immortals of medical science.

William Hunter was never married; his fiancée, a daughter of Dr. Douglas, died shortly after they became engaged.

The two brothers William and John Hunter stand out not only among men of medical science of their own time but may be compared with those of any time without suffering from comparison. While John was undoubtedly the greater, William shines as an anatomist and as the discoverer of the absorbent system.

Difference in the Probabilities of Longevity Between Living in the Country and in Great Cities

The accompanying table, photographed from a page of the *London Magazine and Gentlemen's Monthly Intelligencer,* published in March, 1772, shows that relative expectation of life was studied as long ago as that date. A paragraph comments on the table as follows:

"Dr. Price, in his observations on reversionary payments, has published five tables showing the probabilities of life, in the district of Vaud, Switzerland, in a country parish in Brandenburgh, in the parish of Holycross near Shrewsbury, at London, at Vienna, and at Berlin. 'My chief purpose (says he) in giving these tables is to exhibit, in the most striking light, the *difference* between the state and duration of human life, in *great cities* and in the *country*. It is not possible to make a comparison without concern and surprise. I will here beg leave to lay it in one view before the reader, desiring him to take with him this consideration, that (for reasons elsewhere explained) it can be erroneous only by giving the difference much too little.' "

The first division of the accompanying table gives the proportion of inhabitants dying annually in the places mentioned above; the second section shows the "ages to which half the born live"; the third, the proportion of the inhabitants who reach eighty years of age in the various localities studied; the next, the probabilities of living one year in each of the places; and the last, the expectations of life. This at birth is significant enough to quote: in Vaud the expectation of life at birth is estimated at thirty-seven years; in the country parish of Brandenburgh, thirty-two and a half years; at Holycross, thirty-three and a quarter years; in London, eighteen years; in Vienna, sixteen and a half years; and in Berlin, eighteen years. We cannot help but draw the conclusion that London, Vienna and Berlin were not, at least in 1772, the most desirable places to be born in or to live in.

Oath of the Hindu Physician.—You must be chaste and abstemious, speak the truth, not eat meat . . . care for the good of all living beings: devote yourself to the healing of the sick . . . do the sick no harm; not even in thought seek another's wife or goods; be simply clothed and drink no intoxicant; speak clearly, gently, truly, properly; consider time and place; always seek to grow in knowledge. . . . Do not treat women except their men be present; never take a present from a woman without her husband's consent. When the physi-

cian enters a house accompanied by a man suitable to introduce him, he must pay attention to all the rules of behavior in dress, deportment and attitude. Once with his patient, he must in word and thought attend to nothing but his patient's case and what concerns it. What happens in the house must not be mentioned outside, nor must he speak of possible death to his patient, if such speech is liable to injure him or anyone else. . . . In face of gods and man, you can take upon yourself these vows; may all the gods aid you if you abide thereby; otherwise may all the gods and the sacra, before which we stand, be against you; and the pupil shall consent to this, saying, "So be it."

An Early Description of Malaria in Canada

THE HONORABLE WILLIAM RENWICK RIDDELL,
LL.D., D.C.L., F.R.H.S.
Toronto, Canada

It is well known that the curse of what is now the Province of Ontario was in early times malaria, fever and ague—country fever, as it was called from its prevalence throughout the whole country. But long before Ontario or its predecessor Province, Upper Canada, was born—long before Canada was British, indeed—the mosquito had got in his fiendish work and what was afterwards known as malaria was all too well known to our French precursors.

The earliest description of the disease in our country known to me is that given in 1684 by Baron de la Hontan, a Gascon nobleman who, embarking at la Rochelle, came to Canada from France in 1683. His letters from Canada to an old relative in France have been frequently published—an excellent and cheap edition appeared in Paris in 1900—*Un Outre Mer au XVIIe Siècle—Voyages au Canada du Baron de la Hontan, par M. François de Noir.*

He visited Fort Frontenac, now Kingston, Ontario, in the summer of 1684; and in his Letter VII, he gives the following:

M. de la Barre (the Governor of Nouvelle France) joined us toward the end of August . . . he was attacked by a fever which developed rapidly, and his Esculapius had already pronounced sentence of death. The disease also attacked the soldiers whom M. de la Barre had brought with him. . . . This kind of fever, intermittent as it was, had all the power necessary to carry the sick post haste into the next world. In the chill, the convulsive movements, the shivering and the rapidity of the pulse were so violent that the greater part of the sick died in the second or third attack—their blood was brown, verging on black mixed with a kind of yellowish serosity which was not dissimilar to pus.

We asked M. de la Barre's doctor the cause of these symptoms and he, like a clever man sustaining the reputation of his masters and his confrères, dazzled us by his big words. Never did Hippocrates or Galen use finer language concerning the cause of fever. "This disease," he said, rubbing his forehead and with all doctoral authority depicted on his face, "this disease can be attributed only to the bad quality of the air and food . . . the air being too rarefied by the rapid movement which the excessive heat causes in the vapors, one does not take in enough for sound and hearty respiration. Moreover, what little air is taken and pumped in by the pulmonic tubes being charged with contagions and minute impure bodies, throws one's nature into a fatal derangement. Besides, brandy and salt meats turn the blood sour: this sourness . . . causes a coagulation of the chyle and the blood when they mingle in the veins: this coagulation thickens it and prevents it passing in the heart as quickly as usual—that produces an extraordinary fermentation and there you have the fever of Fort Frontenac."

La Hontan, charmed as he was with the doctor's lucid description—coagulation of the chyle producing thickening, thickening preventing passage, etc.—yet permitted himself to doubt—for why, if the oracle was true, were not all the inhabitants of the fort attacked? Why only the soldiers?

He tried a conjecture of his own. The soldiers coming up the river from Montreal, not being skilful enough to pole their canoes along, had to jump out continually into the water to pull them up the Rapids. Now, the water being naturally cold and the heat excessive, the blood might very well be chilled by antiperistalsis and apparently cause revolutions in nature which would produce these fevers—if, at all events, it is true, as the saying runs, *omnis repentina mutatio periculosa est* (every sudden change is dangerous).

He had to give up this theory when, after being chaffed about his old and superannuated "antiperistalsis" (reaction), he was asked to account for de la Barre being attacked when he had never once jumped into the water.

The doctor's theory—or for that matter la Hontan's own—was as good as any till but the other day. For instance, in Hooper's *Medical Dictionary,* Dr. Grant's edition, London, 1848, we find: "It seems to be pretty generally acknowledged that marsh miasmata or the effluvia arising from stagnant water or marshy ground when acted on by heat are by far the most frequent exciting cause of this fever." And I can bear personal testimony that that was the approved theory in Ontario, half a century ago.

La Hontan does not give the treatment: the "antiperiodic" virtues of cinchona, known for the first time to any white in 1638, were probably unknown to de la Barre's "Esculape." However that may be, although he had already pronounced the sentence of death on him, his patient came around in a few days.

I was struck with the malignity of the disease as described: but the pernicious malarial fever described by Sir William Osler: *The Principles and Practice of Medicine,* fifth edition, p. 215, was not rare in old Canada—this seems to be the type seen at Fort Frontenac.

Osgoode Hall.

Editorial Articles

INDUSTRIAL ACCIDENTS TO YOUNG WORKERS

"Youth is a special hazard in industrial employment and as such entitled to special protection by the law. This principle, already expressed in legislation in a number of states forbidding the employment of children under sixteen, and to some extent under eighteen, in the operation of certain dangerous machinery, must be further extended if grave economic, social and individual waste is to be avoided."

In these two statements, the chief conclusions of an analysis of industrial accidents to minors in three states, made by the Children's Bureau of the United States Department of Labor, are summarized. This report presents the results of a study of industrial injuries to employed minors in Wisconsin, Massachusetts and New Jersey, with special reference to the causes of the injuries and to their economic and social effects.

These three states give their young workers a considerable degree of special protection. Yet the records covering a period of twelve months in each state show a total of 7,478 industrial accidents to employed minors, resulting in 38 deaths, 920 cases of partial disablement for life, and 6,520 cases of temporary disablement. These 7,478 cases represent, moreover, only those minors who were entitled to compensation under the law, and concerning whose injuries, therefore, complete records were made. So the total number of injured was much larger than these figures show.

Analysis of the injuries sustained by cause showed that machinery, the most frequent cause of injury, was responsible for more than a third (36.2 per cent.) of the injuries. In Massachusetts and Wisconsin it caused twice as high a percentage of the accidents to minors as of the accidents to workers twenty-one years of age and over, notwithstanding the fact that the employments forbidden to young boys and girls are chiefly the operation of dangerous machines.

Handling objects was the second most frequent cause of injury in all three of the states covered by the study. The most serious results of handling heavy objects are strains, the number of which could be reduced by prohibiting young workers from doing work that involves heavy lifting. There were 122 cases of hernia recorded resulting from strains. Another class of objects handled, namely, sharp or rough objects, was the cause of many injuries. Although many of these injuries were slight in themselves, infection developed in a large proportion of them.

Among all the causes of industrial injuries to minors, falls of persons ranked third in the number of injuries caused. Seven deaths were due to falls, but the percentage of permanent partial disability from this cause was comparatively low.

A noteworthy fact about injuries caused by vehicles, the fourth most important cause, was the large number due to cranking the engines of automobiles. So many of these caused fracture that the duration of the consequent disability was long. The proportion of deaths and permanent partial disability resulting from injuries caused by vehicles was higher than for any other cause except machinery and electrical shock.

The Children's Bureau report concludes as follows:

"Industrial risks for minors as well as for adults can be reduced by requiring more adequately guarded machinery and safer work places, but the findings of this study indicate that for young workers special dangers exist. One is indicated by the high proportion of injuries in which infection developed. If this proportion is to be decreased the natural carelessness of youth must be overcome. Although this would not reduce the number of injuries, it would prevent many of them from disabling the young worker. Another danger is seen in the high proportion of the injuries to minors due to machinery. The analysis which this report presents of accidents to minors in three states shows not only the large number of machine injuries but their severity. It shows also the great need of further protection for boys and girls sixteen and seventeen years of age whose employment—particularly in the operation of dangerous machines—is far less safeguarded than is the employment of younger workers."

GOITRE AND CARDIOVASCULAR DISEASE

Goitre has been much to the front in recent years and the condition has been found to be greatly more prevalent than had been supposed. In the *Boston Medical and Surgical Journal,* September 17, 1925, Dr. Frederick A. Coller, of the Department of Surgery of Michigan University, writes on the subject, attributing to endemic goitre certain diseases and conditions of ill health, including malignant disease. He states that goitre is a precancerous lesion with an incidence of malignancy of, at least, three per cent.

However, the condition to which it is proposed to direct attention in this editorial is the damage done to the cardiovascular system by endemic goitre in

the production of heart disease and the suggestion that as much notice should be paid to goitre as a factor in the bringing about of heart disease as to syphilis and rheumatism. This reads as a reasonable argument and perhaps it may be carried somewhat further. It seems to lend weight to the hypothesis that endemic goitre and rheumatic disorders are allied.

A great deal has been written of late concerning the evil effects of high blood pressure and hyperthyroidism, but the subject of low blood pressure and subthyroidism has been comparatively neglected, although interest is now being aroused in this phase of the question. The terms low blood pressure and subthyroidism if not identical are frequently coincidental, while subthyroidism is coming more and more into the limelight as predisposing to certain diseases, notably to goitre and some forms of rheumatism. As is well known, there are forms of goitre not associated with hyperthyroidism. These are parenchymatous goitre, in which there is a general increase in normal thyroid tissue; colloid goitre, in which the quantity of colloid is excessive; cystic goitre, due to degeneration of the walls in colloid goitre, and fibrous goitre resulting from inflammatory changes. Also it has been mooted recently that a subthyroidic taint in parents subjects their offspring to a special tendency to rheumatism and perhaps rheumatic fever, as well as to the rheumatoid or atrophic and osteoarthritic or hypertrophic types of arthritis deformans. Of course, rheumatism and especially in children is a potent, some say the most fruitful, cause of heart disease, and therefore it would seem that in fighting subthyroidism or thyroid instability we are fighting to prevent heart disease, on sound and plausible premises.

Thus there appears to be a basis for the hypothesis that there is a relationship between endemic goitre and rheumatism. Again, deficiency of the mineral salts, constituents of our bodies be it remembered, causes diseases of various kinds, delay of growth deformities and wasting diseases of youth and of adult age. For example, iodine, which recent investigations have shown to be one of the most important of these salts and its lack in the thyroid the cause of that condition known as hypothyroidism, is believed to be responsible for or a leading factor in the causation of many of the most common and severe maladies. It has been practically proved that endemic goitre is due to deficiency of iodine in the thyroid gland.

It is suggestive in this connection to note that Michigan, of which Dr. Coller is a resident, is a part of the iodine starved belt of this country, and that the use of iodine in small doses has been encouraged there since the beginning of the year. The prevalence of hypothyroidal conditions is wider by far than is generally supposed, not only in country districts lacking in iodine, but in cities and towns in which sophisticated food denuded largely of its mineral salts including iodine is the diet, as a rule, of the mass of the people, hypothyroidal or goitrous conditions, or conditions bordering on goitrous, are more or less frequent.

Several peculiarities of rheumatism seem to suggest a link with goitre and more certainly with hypothyroidism. Dr. Coller has done well to point out that endemic goitre appears to synchronize with heart disease, or rather that endemic goitre damages the cardiovascular system. As heart disease is now the most prevalent and deadly disease, it is fitting that every probable or possible means should be sought to prevent it. The field of hypothyroidism appears fruitful in this direction.

LUES AND LUETISM

Syphilis is undoubtedly the origin of much disease and ill health. Figures as to the incidence of syphilis are extremely conflicting, some medical statisticians placing them very high, others putting them quite low. As a matter of fact there are no reliable data on the subject and it is a matter regarding which information is called for.

In the effort to clear up some of the moot points with respect to syphilis, Dr. Eugene Hertoghe of Antwerp and Dr. William Seaman Bainbridge of New York wrote an article on the subject which was published in the *Franco-British Medical Review,* January, 1925, referred to in this journal, and which they followed up by another article in the *Franco-British Medical Review.*

The authors developed the thesis that in addition to the accepted types of specific disease, congenital and acquired, there is a much attenuated form of syphilis which may have been modified by passing through a number of generations, which may react to none of our present day tests for specific disease, but which is present as an important element in numerous cases. This type of thinned out lues the authors have termed luetism, a taint not passed by contact, nonreactive to present day tests, but a factor in many and widespread morbid reactions and almost nonselective in its points of attack.

The authors particularly insist upon the point that to no one cause can all disease be attributed suggesting that disturbed endocrine activity, metabolic dysfunction, chronic intestinal stasis, with toxic conditions, focal infection and luetism are more or less interrelated.

They believe that there is cumulative evidence to show that, 1, there is an attenuated form of syphilis, possibly so modified by passing through several gen-

erations as to prove nonreactive to the Wassermann test. 2. This type of syphilis is an important underlying factor in numerous doubtful cases, particularly in some of the ulcerative cases of the gastrointestinal tract, and occasionally in other conditions which exhibit elements of a somatic toxic state. 3. Since the Wassermann test is variable in cases with gross syphilitic lesions, it is logical to assume that it will show far greater modifications in its reactions to an attenuated form of syphilis, the thinned out type which the authors term luetism. 4. The favorable results obtained from iodine medication in goitre, and from bismuth medication in gastrointestinal conditions, point to an antiluetic effect of these drugs on a possible underlying factor of luetism. 5. Intensive research might be instituted to discover a test to take the place of the Wassermann. This new test should be so sensitive that it will react to the possible variable types of the spirocheta in the hypothetical gap between our present day negative and this greatly modified type of syphilis. This hypothetical gap is described in the text of the article.

The arguments are suggestive and plausible. Syphilis may be the underlying cause or a factor in many diseases and the argument, applied to certain gastrointestinal disorders which clear up under intensive bismuth medication, because, as the authors point out, bismuth is an antiluetic medicament, sounds reasonable. The question of luetism is one which it seems might be studied with advantage.

X RAYS IN THE DIAGNOSIS OF DISEASES OF THE LUNGS AND PLEURA

Of course, that x rays are an invaluable aid to diagnosis cannot be rightly disputed. On the other hand, it is unwise to belittle well tried clinical methods of diagnosis and to applaud x rays as the only means of detecting with accuracy certain pathological conditions. It seems to be the fashion to regard the older methods of diagnosis as out of date and to look upon the modern modes as all sufficient for the purpose. In a paper contributed to *The Practitioner,* February, 1926, by Dr. David Lawson, a note of warning is uttered on the fallacy of placing too great faith in x rays for diagnosing diseases of the lungs and pleura, for instance. This authority insists that this method can never effectively displace clinical methods and that its rightful position in the armamentarium of the physician is that of complement to the older methods.

The writer states that skiagraphy alone, although it provides us with a permanent record, and may reveal changes invisible by the screen, is singularly incomplete; as there are certain important phenomena of value to the physician which it cannot disclose, and which nevertheless may be detected easily by fluorescent screen examination. It must be always borne in mind that the lung is a tidal organ, of which the physical condition changes with the movement of respiration and further the neighboring organ, the heart, is a mobile organ. Its activity is ceaseless. These fundamental facts are of the nature of a closed book to the photographer. He cannot make use of them but the screen can. The transillumination of the lung, which increases during inspiration and decreases during expiration is clearly discernible on the screen. Many other important points in the diagnosis of lesions or abnormalities of the lung and pleura can be distinguished by screen examination.

The point upon which Dr. Lawson wishes to insist is that too much is often asserted for differential diagnosis by means of radiography alone, and that to get the maximum help the physician and the skiagrapher should always, where possible, collaborate and examine the patient together by means of the fluorescent screen in the dark room.

THE TONSILS

The why and wherefore of the tonsils is still very much of a mystery. They have been of especial interest to school medical inspectors because of the importance to the health of the child, of their condition, and it has had much study at the hands of such inspectors in England where the men are better equipped for research than our own school medical officers, who usually are poorly paid part time men, with little inclination to studies of this nature.

Dr. H. Leslie Cronk, in his little book on *School Medicine,* has given a most interesting summary of what has been advanced, with any show of foundation, in regard to the function of the tonsil. He believes there is an intimate relation between the thyroid and the lymphatic tissue, including the tonsils, and that inadequacy of thyroid secretion is connected with overproduction of lymphatic tissue and enlargement of the tonsils. "There is experimental proof that administration of thyroid extract may diminish the size of adenoids and enlarged tonsils."

In his school studies he found that there was a rise in incidence of enlarged tonsils in close correspondence with periods of acceleration in growth and he puts forward the hypothesis that "in the past stages of evolution puberty took place earlier than it does now, the postponement occurring *per saltum,* and that it has advanced in boys one stage more than in girls. Before puberty is attained there is a great increase of weight of the body, and this increase remains marking the almost obliterated previous pubertal periods. To bring about this great increase in body weight the lymphatic tissue is produced in excess for a year or two previously and the catabolic func-

tion of the thyroid diminished; as the latter increases the former diminishes and increase in growth occurs. There is thus a period of anabolism with activity of lymphatic tissue favoring nutrition and diminished growth; the thyroid then wakes into activity, leading to the decrease of the lymphatic tissue, increased metabolism, and rapid growth in both height and weight.

"There are one or two interesting facts as regards enlarged tonsils which fit into this scheme quite well. It is well known that enlargement of the tonsils runs in families; numerous cases have come under my own observation, but I think the fact is too well known to need more than mention. Of course, this may only mean similar external circumstances have been acting, but when it is taken into account that families with enlarged tonsils live next door to those without it is more plausible to suggest some hereditary condition or some dietetic distinction. That there is such hereditary transmission of thyroid inadequacy is probable. Secondly, enlargement of the tonsils has been found to occur more frequently among children with little fingers incurved in the manner seen among Mongolian imbeciles.

"Thirdly, the relatives of children with goitre fairly frequently have incurved little fingers and still more frequently have enlarged tonsils. All these facts closely connect hypertrophy of the tonsils with thyroid inadequacy.

"The bases for the ordinary view of tonsillar enlargement are obvious, and some of the arguments require consideration. First, most enlarged tonsils are infected. This is shown in many ways and most clearly, perhaps, by their association with enlarged cervical glands. Statistics have been collected and published showing this relationship which, since it is an uncontested experience, need not be quoted. It is sufficient to remember that the size of the tonsil does not determine the size of the cervical glands, and that numerous cases of quite wellmarked hypertrophy of the tonsils are met with in children whose cervical glands could hardly be called abnormal. On these grounds, among others, it must be concluded that few enlarged tonsils escape infection, but this does not necessarily mean that the infection is the cause of the hypertrophy. The source of the infection has been variously stated; the most frequently cited are carious teeth, colds, and the exanthemata."

With regard to the treatment of tonsils he says: "About the only reasons for removing tonsils will be the presence of chronic cervical adenitis, recurrent tonsillitis or quinsy, and, occasionally, the presence of a remote disease of a chronic nature, which may be kept going by septic tonsils, and where no other focus can be ascertained. If these principles are adhered to the results of the operation will be, almost invariably, good. The prevention of tonsillar infection will include removal of any causes local, such as carious teeth, chronic nasal catarrh, etc., or general, such as the exanthemata, and early cure of hypertrophy by medical means if possible. I think that an effort should be made on a sufficiently extensive scale to treat enlarged tonsils in young children with iodine or thyroid extract and compare the result with those not treated, having special regard to respiratory affections and infections of the tonsils."

THE INCREASE OF APPENDICITIS

It is but a few years ago that appendicitis became known as a disease. The first operation for appendicitis was done in Boston some thirty years ago. Formerly the disease was generally fatal because it developed into peritonitis. Appendicitis is becoming more common and it is asserted by some that it is one of the diseases due to the diet of civilization.

In the *New Health Society Bulletin* for March it is pointed out that the condition is practically unknown among primitive races and that English surgeons practising among the hillmen in Northern India and among the negroes in Central Africa report often that they have to do a considerable number of appendicitis operations among Europeans but not among the natives. It is argued that if it is a germ disease it should obviously spread from the Europeans suffering from appendicitis and living in Central Africa, Northern India and so on to the natives in their vicinity. It is suggested that the undoubted increase of appendicitis in civilized and among white men in uncivilized countries is owing largely to the denaturalized and unsuitable foodstuffs which form a goodly proportion of the white man's diet. For example, Europeans living in India, Central Africa and in other primitive regions into which they have intruded bring with them the food of civilization and live largely on chemically bleached, highly refined white flour from which the husk containing the vitamine content has been carefully removed, on canned meat, canned vegetables, canned milk and other similar foods.

While the exact cause of appendicitis is unknown it is known that it is most frequent in towns, rare in the country and extremely rare in primitive districts in which the natives live on a natural simple diet. These facts lead to the suspicion that socalled civilized diet is a ruling factor in the causation of appendicitis. There is little doubt that in the towns of this country denatured food is eaten to a large extent and it does seem likely that this kind of food may be largely responsible for the many cases of this painful and not infrequently fatal malady.

News Items.

New X Ray Equipment.—Long Island College Hospital has recently had installed a complete high voltage x ray equipment with lead wall protection.

Professor Osborn Honored.—Prof. Henry Fairfield Osborn, for many years president of the American Museum of Natural History, New York City, has been made a Fellow of the Royal Society of England.

Mental Hygiene Clinic Reorganized.—The mental hygiene clinic of Hudson Guild, New York City, has recently been reorganized. Its director is Dr. Stephen P. Jewett, of the Bureau of Children's Guidance.

Baron Rothschild Here.—Baron Henri de Rothschild, of Paris, well known not only as a pediatrist, but also as a playwright and a philanthropist, is in the United States and will spend several weeks in studying the aspects in this country of his special activities and interests.

Dr. Cogswell's Diary.—The Yale University Library has recently received an interesting and valuable gift in the original manuscript of the diary of Dr. Mason Fitch Cogswell, Yale, 1820, of New Haven.

To Study Out Patient Clinical Methods.—Michael M. Davis, Jr., Ph.D., executive secretary of the United Hospital Fund of New York, has sailed from New York to spend several months studying out patient clinical methods in the hospitals of Europe.

Health Survey of Constantinople.—Dr. Ralph K. Collins, of Trinidad, Colo., has been sent by the Rockefeller Foundation to make a health survey of Constantinople and to escort back to this country a group of native Turkish physicians and nurses to study local health methods.

Gift to Baker Laboratory at Cornell.—Announcement was recently made of a gift of $30,000 from George F. Baker, financier of New York, to be used in the Baker Laboratory of Chemistry at Cornell University. The laboratory, costing $1,500,000, was the gift of Mr. Baker a few years ago.

Mental Hygiene at Brown University.—Announcement has been made by the president of Brown University, Dr. W. H. P. Faunce, that for next year two trained psychiatrists have been engaged to devote their services to the study, care and treatment of the mental life of the undergraduates at the university.

Portrait of Dr. Francis.—The Presbyterian Hospital in New York City has recently been the recipient of a valuable portrait of Dr. John Wakefield Francis, painted by John Trumbull. The picture was given to the hospital by Mr. and Mrs. John Jay Chapman to be hung in its new home in the new Medical Centre.

Streets Named After Eminent Physicians.—Dr. John J. Nutt, of New York, has written a letter to *New York Medical Week* making a suggestion that the streets and squares in the neighborhood of the city's new Medical Centre be named after some of America's eminent physicians. He quotes the French precedent for this procedure.

Sturgis Research Fund Increase.—The Sturgis Research Fund of the Burke Foundation, for applications in the convalescent field, has recently had its endowment enlarged through a gift from its founder and by proceeds from sales of the products of occupation work by the patients. The fund, with the aid of the American Heart Association, is making a second study of the results of neuromental convalescence.

Memorial to Walter Reed.—The little town of Belroi in Gloucester County, Va., the real birth place of Walter Reed, in cooperation with the Walter Reed Memorial Commission of the Virginia Medical Society, will take steps to have the little house in which Reed was born, now in a dilapidated condition, restored and made a national shrine. The fact that Harrisonburg, Va., is usually given as the great physician's birthplace is probably accounted for by the fact that his family went there from Belroi to take up their residence when he was a mere infant.

Trachoma Among the Indians.—A delegation of ophthalmologists recently left New York City to inspect the Indian reservations in Oklahoma with a view to instituting measures for the cure of the widespread trachoma prevalent among them. The delegation included Dr. Benjamin Franklin Royer, medical director of the National Committee for the Prevention of Blindness, Dr. Arthur M. Yudkin of the Yale University School of Medicine, Dr. William H. Wilder of Chicago, and Dr. Thomas B. Holloway of the School of Medicine of the University of Pennsylvania.

Harvard's African Expedition.—Dr. Richard P. Strong, professor of tropical medicine at Harvard, and seven associates sailed recently from Boston to make a study of African life and to observe the effects of special drugs on sleeping sickness and other diseases prevalent there of men, animals and plants. Others of the faculty of Harvard accompanying Dr. Strong are Dr. George C. Shattuck, assistant professor of tropical medicine; Dr. Joseph Bequaert, assistant professor of entomology; Dr. Glover M. Allen, lecturer on zoology; and Dr. Max Theiler, instructor in tropical medicine.

Gifts and Bequests.—The Union Memorial Hospital, Baltimore, received $25,000 by the will of Mr. John S. Gittings, of Baltimore.

The will of the late Gustav Ulbricht provides $2,000 for the Pasavant Memorial Homes; $50,000 for the New York Association for Improving the Condition of the Poor, and $25,000 to the Cornell University.

The Sharon Sanatorium, Sharon, Massachusetts, and the Central New England Sanatorium and Tumor Colony, Rutland, Massachusetts, received $150,000 by the will of the late Mrs. Thomas O. Richardson.

One thousand dollars was bequeathed to St. Joseph's Home for the Blind, Jersey City, by the late Nellie Lynn, of Phila-

Personal.—Dr. Seymour Oppenheimer, of New York, has temporarily discontinued his practice of medicine and will spend some time abroad investigating plastic and cosmetic surgery of the head, face and neck. Upon his return he will devote himself exclusively to this branch of medicine. Pending his absence Dr. Harold Hays and Dr. Arthur Palmer at 22 West Seventy-fourth Street, will assume charge of his practice.

Dr. René Sand, secretary general of the League of Red Cross Societies, arrived recently for a visit in New York and other cities of the United States.

Miss Katharine G. Ecob, for several years chief field agent of the New York State Commission for Mental Defectives, has recently been made a member of the staff of the State Committee on Mental Hygiene of the New York State Charities Aid Association.

Dr. Walter Timme, of New York, delivered the Emmerling Memorial lecture before the Pittsburgh Academy of Medicine.

Dr. Leon Dufourmentel of Paris has been a recent visitor in New York City.

Dr. M. O. Magid has been appointed visiting surgeon to the penitentiary workhouse for women on Welfare Island, New York City.

Dr. Ross Miller and Dr. J. B. Acker, both of Nova Scotia, have been visiting friends in New York.

Dr. George E. Brewer was guest of honor at a meeting and dinner of the West Side Clinical Society of New York, on May 11th, and made an address on the subject of military surgery.

Dr. Arthur V. Meehan of Brisbane, Australia, has been making a brief visit in New York.

Dr. George J. Doyle has been appointed chief medical examiner for the New York Municipal Civil Service Commission.

Among recent visitors from abroad at the Bureau of Clinical Information of the New York Academy of Medicine, were Dr. Peter Schmidt of Shanghai, China; Dr. Clara Stewart of the Medical School of Leeds, England; Dr. Jamichi Satow of Tokio, Japan; Dr. C. H. Hendry of Soochow, China; Dr. H. H. Waterhouse of Koloa Kanai, Hawaii; and Dr. Miguel C. Algovin of Lima, Peru.

Dr. James J. Waygood, psychiatrist, has been appointed director of the recently established neuropsychiatric clinic for children at St. Christopher's Hospital for Children in Philadelphia.

New appointments to the faculty of the New York Polyclinic Medical School and Hospital include Dr. Jerome M. Lynch, Dr. Austin Cossitt, Dr. Adrian V. S. Lambert, Dr. Robert E. Brennan, and Dr. Edward L. Kellogg.

Dr. Eleanor Van Alstyne has been elected president for the coming year of the Women's Medical Association of New York City.

Dr. Adolph Elwyn, assistant professor of anatomy at the New York College of Physicians and Surgeons, addressed the spring meeting on May 27th of the Association of the Alumni of the College on the subject of the Dawn of Modern Medicine.

Society News and Notes.

At the recent annual meeting of the Pennsylvania Public Health Association, the following officers were elected: president, Dr. William Krusen of Philadelphia; first vice-president, Dr. Carey J. Vaux, of Pittsburgh; second vice-president, Dr. Howard C. Frontz, of Huntingdon; secretary-treasurer, Dr. William C. Miller, of Harrisburg; assistant secretary-treasurer, Dr. Edgar S. Everhart, of Harrisburg. The members of the executive committee consist of the above mentioned officers, together with Dr. Charles H. Miner, Miss Alice O'Halloran of Harrisburg. Dr. W. C. Davison of Kingston, Dr. J. Treichler Butz of Allentown, Dr. Frank J. Small of York, and C. B. Auel of Pittsburgh. The next annual meeting will be held at Pittsburgh, and Dr. Vaux, director of the Health Department of that city, has been appointed chairman of the program committee.

The first annual meeting of the Saskatchewan Health Officials' Association, organized on March 5th, will be held at Saskatoon in July at the same time as the meeting of the Saskatchewan Medical Association. The object of the Health Officials' Association is the promotion of public health agencies and activities, and all salaried public health officials are eligible to membership.

* * *

The Pan-American Red Cross Conference, which began in Washington on May 25th, is in session and will continue until June 5th. Popular health education is the chief topic of the convention.

* * *

Expositions of interest in European cities under the auspices of various local and foreign medical and welfare societies are the Exposition for the Care of Health, Social Care and Physical Exercise now being held in Dusseldorf, Germany; the International Health Exhibition, called very appropriately "Man," in Budapest, Hungary, now open and to run until September; and the International Child Welfare Exposition to open in Antwerp, Belgium, in October. At the Philadelphia Sesquicentennial International Exposition there will be numerous exhibits by public and private health agencies.

* * *

The Travel Study Club of American Physicians will sail from New York City on June 12th. Among foreign physicians who will assist in receiving and entertaining the American delegation will be Prof. Siegert of the University at Cologne, Prof. Vulpius of the medical faculty of Heidelberg University, Dr. De Quervain, dean of the faculty of the University of Berne, and Dr. Rollier of Leysin. Among those who will go from New York and vicinity are Dr. Frederic H. Albee, Dr. Louis L. Seaman, Dr. Richard Kovacs, and Dr. Lulu Hunt Peters.

* * *

A group of fathers, whose wives and children attend the Infant Welfare Centre, Kensington, have been organized since 1921 as a Fathers' Council, according to *Maternity and Child Welfare*. This council works in cooperation with the general committee of the center, aids in eradicating unsanitary conditions and housing violations in the district, and assists in the formation of such councils in other parts of London.

* * *

The French Benevolent Society recently announced its purchase of a large plot in West Thirtieth Street, New York, between Eighth and Ninth Avenues, as a site for a new fifteen story building to replace the present French Hospital at 450 West Thirty-fourth Street. The new hospital will have a capacity of 175 beds.

* * *

The American Society for the Prevention of Cruelty to Animals has distributed an appeal urging citizens of New York to write to their State Senators and Assemblymen urging them to support the bills before the Legislature designed to lessen greatly the suffering of animals trapped for their furs. These bills provide for the inspection of traps every twenty-four hours, the stamping of each trap with the owner's name, and the elimination of nonkilling steel traps after January 1, 1928. Under the terms of the bills traps used after this date must capture the animal alive and unhurt or cause its immediate death.

* * *

The committee for America of the International Stomatological Association, which is now making the preparations for the participation in the International Stomatological Congress to take place in Paris in 1927, consists of the following: Chairman, Alfred J. Asgis, D.D.S.; treasurer, G. Reese Satterlee, M.D.; recorder, E. B. Hardisty, A.B., scientific research, E. C. Rosenow, M.D.; clinical stomatology, Joseph Colt Bloodgood, M.D.; education and legislation, Oliver T. Osborne, M.D.; public health and lay education, William G. Schemeley, M.D.; history of stomatology, George W. Mackenzie, M.D.; bibliography and nomenclature, Anthony Bassler, M.D.

* * *

The New York Electrotherapeutic Society has communicated the following resolutions to the New York City Department of Health:

WHEREAS, Various commercial concerns and enterprises dealing in electrotherapeutic and allied apparatus are with increasing frequency holding public lectures in New York which are in effect and in fact nothing more than lectures advertising their goods; and Whereas, audiences to these lectures are not limited to members of the medical profession; and

WHEREAS, The lectures themselves are not carefully selected or given, and Whereas, the audience must necessarily be misled,

Be It Therefore Resolved by the Executive Committee of the New York Electrotherapeutic Society that the Department of Health should control such lectures by licenses, after due and proper investigation, so that the public may be protected from the aforesaid abuses.

* * *

The American Public Health Association Program Committee has announced as follows the tentative program for the annual meeting in Buffalo in October: Photographs and Other Art in Education and Publicity—a clinic session on the uses and abuses of the several forms of illustration; Posters and Placards—a clinic for the purpose of suggesting the most usable of the poster material supplied by various health agencies and outside publishers; Materials for Child Health Education (joint session with Child Hygiene)—a clinic aimed to arrive at a tentative agreement on a limited selection of materials for class room use; Business and Dinner Meeting—on Monday, the opening night, to which only fellows and members and their guests will be invited; Round Table Sessions—luncheon and dinner gatherings limited to about twenty persons to make it easy for all present to participate; Editors of Health Periodicals—a session for discussion of problems in editing and publishing magazines; Exhibits and Headquarters—a collection of helpful publicity and educational material and opportunity for discussion of individual problems; The Section Council will value suggestions as to topics for round table sessions. Among those being considered are Radio, Newspaper Releases, Getting Volunteers to Do Your Work, Uses of Statistics, Exhibits, House Organs and Film Slides. Such suggestions should be sent to Raymond S. Patterson, State Department of Health, Trenton, N. J. An international tone will be given to the meeting by discussions of tropical hygiene by leaders from Mexico, Central America, and South America, and the presentation of a résumé, supplemented by an exhibit of public health work being done in Russia, by a prominent Russian sanitarian.

* * *

The Society of Neurology of Paris held its Seventh Annual International Reunion, June 1st-2nd, in Paris at the Salpétière. The leading question of the conference was the actual means of exploration of the sympathetic system in clinics and their value. The chief speakers were Dr. André Thomas of Paris, and Dr. Soderbergh of Göteborg.

At the recent annual election of officers of the Section on Dermatology and Syphilology of the New York Academy of Medicine, Dr. Mihran B. Parounagian was appointed chairman and Dr. George C. Andrews, secretary.

Book Reviews

DIETETIC TREATMENT OF DIABETES

Verordnungsbuch und Diätetischer Leitfaden für Zuckerkranke. Von Professor Dr. Carl von Noorden und Professor Dr. S. Isaac, in Frankfurt am Main. Mit 172 Kochvorschriften. Zum Gebrauch für Arzte und Patienten. Dritte und vierte verbesserte und vermehrte Auflage. Berlin: Verlag von Julius Springer, 1926. Pp. 135.

The frequent revisions within a comparatively short space of time is plain proof of the popularity and appreciation of this very practical little handbook on the dietetic treatment of diabetes for both physician and patient. This edition is enriched by the addition of some points of practical importance and the usual dietary régime followed by the authors in conjunction with insulin therapy.

The food of the diabetic is divided into two groups: 1, the main diet, consisting of foods free from and poor in carbohydrate, and 2, the additional diet, consisting of foods containing carbohydrate. The foods rich in fat are grouped separately. Special attention is called to the table which shows, in addition to the albumin, fat, and carbohydrate contents of various foods and their caloric values, the socalled white bread units and white bread values of carbohydrate foods. Pieces of white bread weighing twenty gm. are taken as the standard (unit). This is based on the principle that the diabetic diet usually includes a certain amount of white bread, and in order that the patient may have some choice and variation in his diet, he may substitute for the white bread carbohydrate foods of the same value. For example, 180 gm. of potatoes have the same white bread value as sixty gm. of white bread. This choice is made easy by the table of the carbohydrate equivalents. This is a new feature of this edition.

Suitable menus are described and the various types of diets are given. A special chapter is devoted to the diet used with insulin treatment. The last part of the booklet is devoted to instructions for the preparation of foods.

SYPHILIS

Le Traitement de la Syphilis par le Bismuth. By Dr. Georges Drouet. Third Edition, Entirely Revised. Paris: A. Maloine et Fils, 1926.

In this monograph Drouet considers in detail the subject of the treatment of syphilis by bismuth. Having been one of the pioneers in this work, his opinions and conclusions may be considered authoritative. The French reading syphilographer will find a vast fund of information in this little volume, not only of a theoretical character, but also of the most practical kind. The author has aimed particularly to make this a practical work, and the reader will find little to find fault with on this score. The work is eminently practical in scope.

In discussing the technic of bismuth therapy the author stresses the dangers inherent in the intravenous administration of bismuth. He states, however, that colloidal bismuth and the soluble tartrobismuthates are being used intravenously. The intramuscular injection is his method of choice. The author emphasizes the interesting fact that patients who are intolerant to repeated injections of a certain bismuth salt will readily tolerate a different bismuth preparation. This is particularly important in cases which have shown an intolerance to the arsenicals. The mere change from one preparation to another seems to be of great value in these cases.

Syphilologists employing bismuth in their practice will find it extremely profitable to read this little work. It will well repay the time devoted to it.

SANITATION AND HYGIENE

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D., Dr. P.H., Professor of Hygiene, University of Pennsylvania. Eighth Edition, Enlarged and Thoroughly Revised. Illustrated with 154 Engravings and four Plates. Philadelphia and New York: Lea & Febiger, 1926. Pp. viii-616.

The eighth edition of this most popular book on the subject of hygiene and sanitation has been published to keep in step with the most recent advances in this field. The necessary revisions have been made and two entirely new chapters have been added. One is the chapter on transmission of diseases, which indicates the different ways in which the various infections spread from one individual to another and their importance. The other new chapter deals with tourist and vacation hygiene and camp sanitation and contains much valuable advice to those who indulge in outdoor life. The chapter on military hygiene has been omitted. Other new features in this edition include discussions on prenatal hygiene, habit and social hygiene, heliotherapy, and the means of prolonging life by hygienic measures.

The author has given us a book of superior quality, concise, practical, interesting to read, up to date, and to the point.

DISEASES OF THE MOUTH AND THROAT

Verletzungen und chirurgische Krankheiten der Mund- und Rachenhöhle, des Halses einschl. der Speichedrüsen, der Speiseröhre, des Kehlkopfes und der Trachea. Von Professor Dr. Paul Clairmont, Vorstand der Chirurgischen Klinik in Zürich. Mit 97 Textabbildungen. Diagnostische und therapeutische Irrtümer und deren Verhutung, Herausgegeben von Prof. Dr. Schwalbe, Geh. San.-Rat in Berlin. Siebentes Heit. Leipzig: Verlag von Georg Thieme, 1926. Pp. 188.

This treatise on the injuries and surgical diseases of the mouth and pharynx and the throat, including also those of the salivary glands, esophagus, larynx and trachea, is based on the vast experience of Paul Clairmont and a review of the most recent literature. The style of the author is attractive and he has succeeded in giving a clear presentation of the subject. The illustrations are numerous and beautiful, being photographs of the author's cases and some selected from various other authors. Every surgeon will find much valuable material in these pages, and even the general practitioner will be benefited by the very simple diagnostic methods suggested. These are especially instructive as there is usually much room for diagnostic and therapeutic errors in the diseases of the mouth and throat. Carcinoma of the various organs is given particular attention. The chapter on goitre is especially commendable.

PUBLIC HEALTH ENGINEERING

The Principles of Public Health Engineering. By Earle B. Phelps, B.S., Professor of Sanitary Science, College of Physicians and Surgeons, Columbia University; Formerly Associate Professor of Chemical Biology, Massachusetts Institute of Technology. New York: The Macmillan Company, 1925. Pp. viii-265.

In this book the author provides in somewhat condensed form a course in Public Health Engineering first offered at the Columbia University Summer School in 1924. It is intended for two classes of advanced students: for the medical health officer who has had little or no engineering training and for the sanitary engineer well versed in engineering, but with insufficient knowledge of the principles of public health. The author has attempted to treat of principles rather than of practice. After twenty-five years of experience along these lines he is well fitted to present the subject matter in suitable form.

The introductory chapter is concerned with environmental conditions and their effect upon public health. The other subjects discussed include atmospheric pollution, the ventilation of buildings, the municipal water supply and the methods of rendering it pure and potable, sewerage and the methods of handling it, the pasteurization of milk, and the lighting problem. The chapter on miscellaneous environmental control includes such subjects as the collection and disposal of municipal refuse, mosquito control, and fly control. Each chapter has a bibliography of references and collateral reading, which are very helpful and make this book valuable for home study.

The author has accomplished a creditable piece of work and the book may well be recommended to those interested in the subject.

CYSTOSCOPY

Operative Cystoscopy. By E. Canny Ryall, F.R.C.S., Founder of and Senior Surgeon to All Saints' Hospital for Genitourinary Diseases, London. With 115 Plates Containing 670 Original Illustrations of Which 528 Are Coloured. St. Louis: C. V. Mosby Company, 1925.

This unusual volume fulfills a long felt want in the realm of American urology. Textbooks galore have been written, all dealing with the subject of urology in the usual manner, but they have failed to deal with operative cystoscopy as a major factor in urology. In the volume under review, the author has confined himself to the operative aspect of cystoscopy, revealing in full measure the many possibilities inherent in the skilful use of this instrument.

Operative measures applied to the ureters, bladder and prostate are fully considered. A brief explanatory text occupies the front part of the book. This part of the work will be found almost as useful as the illustrated plates themselves. Complementing each other, the text and plates form a most valuable combination, giving the reader a complete picture of the clinical conditions.

The plates are unusually beautiful and truly represent the intravesical picture as seen by the artist, Thornton Sheills, through the cystoscope. There is not the least tendency to exaggeration of line and color so often encountered in works of this kind.

The work being really international in scope and character, the legends facing the plates appropriately are given in three languages, English, French and German. The operative methods advised are conservative yet modern in the highest degree. To the urologist and, even more so, to the general practitioner and surgeon, who desires to utilize his cystoscope to its utmost, this handsome volume can be heartily recommended, as perhaps the best of its kind. It is not too much to say that a careful study of this work is as good as most postgraduate courses and better than some.

DIGESTIVE PROCESSES

Methoden zum Studium der Funktionen des Margendarmkanals. Von F. Uhlmann. Handbuch der biologischen Arbeitsmethoden, Teil 6, Heft 2. Berlin und Wien: Urban und Schwarzenberg, 1925.

This monograph by Uhlmann contains a detailed description of all the methods used in the biological studies of the digestive processes. Animal experiments as well as methods used in determining the different functions in patients are thoroughly discussed. Cannon's röntgenographic studies on intestinal mobility, the duodenal tube, also the intestinal tube, are fully described. For physicians interested in the physiology of digestion the present volume is highly valuable.

KIDNEY DISEASE

Kidney Disease from the Physician's Viewpoint. By Rolfe Floyd, M.D., Junior Attending Physician and Pathologist to Roosevelt Hospital, New York. New York: James T. Dougherty, 1926. Pp. vi-181.

In this monograph a clinician endeavors to present whatever is necessary for the understanding of kidney disease by clinicians. No new material is offered, but whatever is known is presented in a masterful and critical manner. It treats of most of the bilateral renal conditions but does not take up the socalled surgical kidney.

In spite of a vast amount of study devoted to the diseases of the kidney ever since the epoch making work of Bright, there is still some confusion in the classification of these diseases when it comes to true and essential distinctions that would bear the tests of analysis and time, and the further attempt to get a good clinical classification that would correspond completely with a good pathological classification has failed up to the present time. The stumbling block seems to be our ignorance of how the kidney elements (the glomerulus and the tubular elements) perform the kidney functions. The goal is a proper correlation between our knowledge of renal lesions and a better understanding of renal symptoms and functions.

The plan of presentation is as follows: The two classifications of kidney disease, Delafield's and Volhard and Fahr's, which the author believes to be the best, are taken up and they are compared critically as to their agreements and differences. Normal kidney function and the failures of kidney function in disease, including nitrogen and salt retention, and the symptoms resulting from these retentions, as well as the symptoms which have been mistakenly thought to be uremic, are described next. The problem of dropsy is then discussed. Hypertension is next defined, its results described and some of its causes are discussed. The nephrosis of Volhard and Fahr, so widely discussed today, is critically analyzed, and the more recent views of Epstein, who injects the element of a possible derangement of the protein threshold as a factor, are presented. The author then at-

tempts to tell what the modern term nephritis means and how this lesion may be recognized during life. The significance of renal function tests is discussed. The purpose, basis and difficulty of renal classification and a review of groups of renal disease are presented and the author comes to the conclusion that there is nothing new to be said on the subject, and that we must return to the bedside, the laboratory and the necropsy and secure more information before the diseases of the kidney can be better understood. In the meantime we must be more particular in regard to the use of the terms we employ. Consequently the treatment must be symptomatic at present and a very brief outline of the methods used is given. A bibliography, upon which the author bases his work, is appended.

This monograph will admirably serve the purpose of acquainting the clinician and general practitioner with all that he should know of the fundamental principles of kidney disease.

THE BUSINESS SIDE OF MEDICINE

Betterman II on the Business of Medicine. By Charles Elton Blanchard, M.D. Youngstown, Ohio: Medical Success Press, 1926. Pp. 249.

This second work by Dr. Blanchard in which he employs the literary device of expressing his own opinions through the fictitious Dr. A. Betterman, is as good reading as his first of the same type, *The Letters of Dr. Betterman.* The author states in his preface that he makes use of this device in order to lend the book "some small measure of humor and human interest that would not have been possible in discussing the subject in the form of a dry essay."

Dr. Blanchard is an ardent advocate of the principle that medicine should be an actual social service and not a business, and this is the message that he endeavors to convey in Betterman II on the Business of Medicine. "Just now in this transitional period of medicine," he writes, "when health service is coming to be more and more a collective effort, publicly paid, the economic side of medicine is of great concern to the profession. Our journals are publishing many articles about it, and at meetings of doctors in their societies the man who can talk intelligently about the business side of medicine is always certain of very flattering attention. It is hoped that this book will fit in just now and serve a good purpose in carrying to both physician and layman a larger fund of information about the subject."

Some of the subjects discussed are: the direct appeal, schools of medicine, including homeopathy, Christian Science, the Hahnemann School, osteopathy and chiropractic, and Mormonism; "straws that point," including the Henry Ford Hospital, the Sharon Health Association in Kansas, the social and health service of the Endicott-Johnson Shoe industry, the Life Extension Institute, etc.; evidences of medical chaos; present status of medicine; medical fads and fancies; how medical progress is made; and medicine in a new day. The appendices contain miscellaneous material, including some poems by the author and further data on some of the medical frauds and fallacies mentioned in the text.

The spirit of Dr. Blanchard's book may perhaps best be rendered by a quotation from its pages. After many months of early professional life went by in the career of "Betterman" in which practice decreased and funds for self and family were reduced to an alarming degree, he writes: "There in my office on those dreary November days and nights I awoke. I came to realize that life is action, fight, struggle. To live is to assert oneself; you in your way and I in mine. Your way or my way of selfassertion may not please the small minds about us, hence the sneer. The worshipper of precedent, the whatever is is right people, the standpatters of every walk of life—none of these could understand your selfasserting or mine. I had selected medicine as my mission in life. . . . I make no apology for it. I heard the call of it. I shall do my work, and I shall be paid for it; paid in money; paid in honor, and in a measure of love. All this was egotism. It had made presidents, put kings on thrones, Napoleons at the head of armies. Some way I would find to assert myself and to command those conditions I needed for my life. I would assert myself as a doctor and let it please or displease whomever it might. By New Year's Day of that year I had found my way, but it made me again a shocking medical precedent breaker—an iconoclast; my idol smashing has never yet been forgiven by some of my professional contemporaries, even now after nearly twenty years have passed and I am getting on into my white years."

In all of Dr. A. Betterman's idol smashing in the service of Dr. Blanchard, we never fail to feel, however we might disagree with some of his statements, that he is perfectly sincere and courageous in his opinions, and that there is often good reason for his belligerent attitude.

Medicoliterary Notes.

The National Tuberculosis Association has recently issued a useful little pamphlet entitled *Planning a Tuberculosis Sanatorium,* by T. B. Kidner. This pamphlet summarizes the latest and best information on tuberculosis hospital and sanatorium planning. Since the whole field of tuberculosis institutional planning has undergone radical changes recently, this publication fills a definite need.

A recent survey of the effects of the prohibition law in Finland, as summarized in a recent German journal, shows that, during the three years of the duration of the law, there has been an increase in drunkenness among the young men and women of cities, while in the case of the majority of the working classes the contrary is true.

Dr. Josef Loebel, a specialist of Czechoslovakia, has recently reclassified the human senses into eleven instead of five. His six extra senses are those of temperature, of pressure, of stinging, of gravity, the power sense, and the kinesthetic sense, which makes it possible for us, even when our eyes are closed, to know in what position our limbs are held.

Public Health Reports for April contains a useful list of nontechnical publications issued by the Bureau of the Public Health Service, covering a wide range of subjects and suitable for popular distribution.

* * *

From the Belgian Congo has just come an amazing account of an important Negro king who sued the hospital at Boma for the possession of his leg, which had been amputated as the result of a serious accident. The King, whose tastes are decidedly cannibalistic, endured the painful operation without a word of complaint, but immediately afterward demanded the severed limb. The surgeons flatly refused. The

king, however, being a powerful person, in his own community, brought suit in the tribunal of Boma and the court has just handed down a decision restoring the severed member to the king. Without further formality, the king took possession of his property and departed for home.—*N. Y. Times.*

Among the new publications on mental hygiene and related subjects are *Suggested Reading in Mental Hygiene,* by Kathleen Ormsby and Dr. Frankwood E. Williams, revised to April 1926; *Mental Defect and Poverty,* by Dr. Thomas H. Haines, reprinted from the 1925 Proceedings of the American Association for the Study of the Feebleminded; and *Understanding the Feebleminded,* also by Dr. Haines, reprinted from the same source.

* * *

The Baby and You! is the title of an attractive leaflet by Dr. Herman N. Bundesen issued as the first of a series of twelve monthly "letters" by Chicago's Health Department.

* * *

The Children's Bureau of the U. S. Department of Labor is issuing a set of six charts on posture standards for boys and girls intended for the use of physicians, nurses, physical education teachers, and clinics. The charts were planned on the basis of extensive observation and measurement of school children by Dr. Armin Klein of Boston, who is in charge of posture clinics for the Massachusetts General Hospital and the Department of Health of the City of Boston. Three types of figures are shown for both boys and girls—the thin, the intermediate, and the stocky, and descriptions of the distinguishing characteristics of excellent, good, poor, and bad posture are printed on each chart.

According to a recent report from the Jewish Telegraph Agency, there has been a serious crime wave during the past year even in Palestine. In 1925 crimes were committed to the number of 19,701, against 16,833 in 1924. Of these 98 were murders and 498 other heinous crimes. There were 36,640 arrests and 18,400 convictions. There are 13,726 persons in prison, 28 of whom are serving life sentences. The police force of Palestine numbers only one thousand and the gendarmerie five hundred in a population of about 800,000.

* * *

Fortschritt und Arbeitserfolg is the title of a new journal which began publication with the number for March 1926. The editor in chief is Dr. O. Schär, of Zurich, Switzerland. The aim of the journal is stated as an effort to establish a closer relationship between the medical profession and science, commerce and industry.

* * *

Prof. Alexander Sholomovitch, director of the narcotic section of the Russian Department of Health, has been making a study of alcoholism in Russia. He is credited with the statement that every year 6,000 Russian workers kill themselves with alcohol. He adds that sixty-five per cent. of all the workers are addicted to intoxicants, and that their average expenditure for alcohol is thirteen per cent. of their yearly earnings.

A new list of summer courses in public health work has recently been published in the *American Journal of Public Health.* This is as follows: Columbia University has shortened its usual six weeks' courses to two and three weeks with accompanying concentration of hours of attendance to accommodate health workers who cannot have an extended leave of absence. The summer session extends from July 6th to August 13th. The following courses will be given: public health administration and rural hygiene, public health engineering, school health inspection, epidemiology, policies and management of clinics, public health law, industrial hygiene, factory inspection, mental hygiene including its personal and social aspects, social hygiene, child hygiene, tuberculosis with emphasis on community aspects, and an introduction to population and health problems. The University of Michigan opens on June 21st for some courses and closes on August 13th. Tuberculosis and the community will be a special study. Other courses will include methods and materials in health education, general hygiene and public health, general sanitation, applied nutrition, principles and practices of medical social work and delinquency, mental hygiene and psychiatry, and community problems. Massachusetts Institute of Technology, through its Department of Biology and Public Health, will give the following courses: methods of teaching general biology, July 6th-August 3d; general bacteriology, July 6th-August 27th; health education methods, July 6th-27th; health records and statistical procedure, July 6th-27th; public health laboratory methods, July 7th-August 13th. The Pennsylvania School of Social and Health Work at Philadelphia will give courses in public health nursing, public hygiene, child health, school health, education, and nutrition.

The Monthly Labor Review for April contains an interesting article by Dr. Frank L. Rector, secretary of the American Association of Industrial Physicians and Surgeons, and editor of the *Nation's Health,* on Physical Examinations in Industry.

* * *

The leading article in *Public Health Reports* for April 9th is on the Public Health Nurse, by Surgeon J. G. Townsend of the U. S. Public Health Service.

* * *

A department of child guidance has recently been organized in the public schools of Newark, N. J., according to the *Mental Hygiene Bulletin.* This department is to operate within the school system a child guidance clinic, and it will also carry on the psychological work of the school system. The organization will include a psychiatrist, a chief of social service, a chief psychologist, adequate clerical personnel, and other workers.

* * *

The American Review for the Blind is the title of a new publication to be issued monthly in revised braille type, grade one and a half, by the American Braille Press, New York. The chief aim of the new journal will be to enable the sightless to maintain contact with current events.

* * *

The George H. Doran Company has announced a new series of books to be called the Humanizing of Knowledge Series. They will aim to carry out the suggestion made by Prof. James Harvey Robinson in his book, the *Humanizing of Knowledge,* that men of science cease to lock away from the layman in textbooks and technical works all the fascinating facts of science, and make an effort to contribute to the world's literature stories of scientific achievements in a form comprehensible to the layman, yet authoritative in subject matter and treatment. The first two titles of the series will be *Starlight,* by Harlow Shapley, and a rearrangement of the *Humanizing of Knowledge.*

* * *

Pygmalion, or the Doctor of the Future, is the latest addition to the Today and Tommorrow Series, published by Dutton. R. M. Wilson is the author.

* * *

Mosquitoes have decided color preferences, according to R. Ko, writing in the *Formosa Medical Society Monthly.* An experiment was made by attaching to a ceiling pieces of colored cloth at different intervals, on which 14,896 mosquitoes, most of them culex, were observed to light. Anopheles and Armigeres preferred yellow, white, deep red, and green. Culex and Stegomyia preferred blue, purple, red and black. The results of the experiment will be applied to extermination methods.

Dr. William Bierman, medical advisor to the National Council of Traveling Salesmen's Association, is the author of an interesting little volume recently published as the instrument for the application of a nation wide medical service for the care of sick travelers. Dr. Bierman was aided in his compilation and preparation of the book by the members of the Board of National Consultants. The "Guide" gives names, telephone numbers and office hours of general practitioners in towns of 10,000 population and over, and similar information about dentists and eye, ear, nose and throat, and genitourinary specialists in cities of 50,000 and over. There are also data on first aid, "when to see your doctor," and "your personal hygiene," and a preventive medical service to which any traveler may send complaints of conditions encountered which are inimitable to physical welfare on trains, boats, in hotels, etc. Dr. Bierman has secured the cooperation of city health officers and the U. S. Public Health Service in remedying such conditions.

The Scientific Proceedings

We present below abstracts of some of the more important papers read at the various section meetings.

SECTION ON PHARMACOLOGY AND THERAPEUTICS

CHAIRMAN, DR. THOMAS ORDWAY, OF ALBANY, N. Y.
SECRETARY, DR. N. M. KEITH, OF ROCHESTER.

The Inefficiency of Most of the Commonly Used Skin Antiseptics.—Dr. Martin B. Tinker and Dr. Henry B. Sutton, of Ithaca, N. Y., presented their findings in a study of various skin antiseptics in common use. Most surgeons, they said, seemed satisfied with their antiseptic technic, yet in reply to a questionnaire nine representative surgeons reported serious infections following clean operations. The average incidence of faulty union ranged from four per cent. to twelve per cent., with the different surgeons of the staff of one of the best organized hospitals. The authors stated their belief that the most frequent source of infection was the skin of the patient. A tabulation of the results of nine investigators of the use of iodine was given showing nine per cent. to forty-five per cent. growth of bacteria from the superficial layers of the skin and ten per cent. to one hundred per cent. from the deep skin. Also a graph and a tabulation of results of investigations were presented, showing over twelve per cent. superficial growth and over forty per cent. deep following the use of picric acid; over eighty per cent. growth with mercurochrome; and one hundred per cent. growth from the deep skin with dichloramine T and with iodine. In striking contrast the authors' tests showed no growth from the superficial skin with chlorinated lime paste and no growth, superficial or deep, following painting with five per cent. acriflavine solution. The solution must be fresh. It was very important, they said, that the bacteriological tests be carried out under conditions as nearly clinical as possible. Blood was frequently present clinically and added greatly to the difficulty in killing streptococcus and probably other germs; this had frequently not been taken into account in testing antiseptics. The laboratory teaching of antisepsis to medical students and nurses had proved conducive to greater care in hospital technic in the authors' experience and the importance of cooperation of laboratory workers was emphasized in further improving surgical results. Their conclusions are as follows:

1. The clinical results of which we have knowledge, from a considerable number of the best organized hospitals in this country, show that serious infections are by no means a thing of the past, and inasmuch as bacteria can be grown almost invariably from skin prepared by the antiseptics adopted as standard in these hospitals, we believe that the inefficiency of these antiseptics should be considered as a possible cause of their troubles.

2. Laboratory studies by a considerable number of investigators have indicated the inefficiency of iodine, the most widely used of the inefficient antiseptics.

3. Personal study of over fifteen hundred cultures (results in most instances confirmed by others) have demonstrated that iodine, picric acid, mercurochrome, kalmarid, will not kill the most resistant, pathogenic bacteria, under conditions of perfect contact, and are still less efficient if penetration is required.

4. Selective action of antiseptics must be considered: because an antiseptic kills one germ, even a resistant one, does not prove that it will kill all, unless all are tested.

5. The aniline dyes seem to deserve further investigation and probably wider use on the basis of apparent germicidal power, penetration, low toxicity, harmlessness to instruments and supplies and excellent outlining of the field.

6. More efficient antisepsis may be hoped for through laboratory teaching of medical students and nurses: more careful scrutiny of technic and cooperation of laboratory workers.

The Treatment of Erythremia.—Dr. Herbert Z. Giffin, of Rochester, Minn., reviewed the various methods which had been employed in the treatment of erythremia, both from the viewpoint of the literature and from personal observation. Twenty-two cases treated with phenylhydrazin hydrochloride were discussed in detail with respect to treatment only; thirteen cases had been collected from the literature to which nine were added.

Venesection, the administration of phenylhydrazin hydrochloride, and radiotherapy were clearly the most effective measures in the treatment of erythremia, he said. Phenylhydrazin by its specific effect in the destruction of red cells reduces the erythrocyte count and the blood volume and brings about more prolonged relief than venesection. Daily doses of 0.2 gm. until a total dose of 3.0 or 4.0 gm. has been given seems to be sufficient for the initial course of treatment. Phenylhydrazin hydrochloride is cumulative in effect, and a reduction in the erythrocyte count continues for as long as two weeks, and sometimes three weeks, after administration. Indications for its discontinuance are a reduction of the erythrocyte count to 4,500,000, a very rapidly developing leucocytosis, or a severe hemolytic crisis. A repetition of the treatment in from one to three months has been necessary, and it is likely that further experience will show that the administration of from 0.1 to 0.3 gm. weekly will maintain most patients in comfort. An inert preparation must be guarded against.

The technic of radiotherapy, both by means of the röntgen ray and radium, has not been satisfactorily

developed, but experience at present indicates that its effect is of a more permanent nature than that of phenylhydrazin, and that aplasia of the bone marrow is not produced. Severe and resistant cases probably can be most effectively treated by means of venesection and phenylhydrazin. One factor of great advantage in the use of these measures over radiotherapy is the ease of administration. Splenectomy for severe gastrointestinal hemorrhage has been successfully performed in one case reported.

The Measurement of the Cardiac Output and Its Variations.—Dr. G. Canby Robinson, of Nashville, Tennessee, said that the principle underlying much of the work directed at the measurement of the cardiac output was set forth in 1870 by Fick, who stated that the minute output of the heart could be calculated by measuring the amount of oxygen consumed by the body each minute and the amount of oxygen removed from each unit of blood as it passes through the capillaries. This principle has recently been applied to men, and an accurate method has been devised by Burwell and Robinson.

A series of observations on normal resting subjects, studied in a half reclining position, has been made. In this series the minute output of the heart varied in different individuals from about three and a half to six and a half litres, and from about fifty to one hundred c. c. per beat. Striking variations were found in the output of the heart of a patient with exophthalmic goitre studied before and after thyroidectomy.

Variations in the output of the heart occurred with change of position, and evidence was presented that diminished cardiac output is beneficial in cases of heart failure. An experimental study indicated that digitalis might produce its beneficial results in some cases by diminishing the cardiac output. The ethyl iodide method of Henderson was briefly discussed.

SECTION ON NERVOUS AND MENTAL DISEASES

CHAIRMAN, DR. JAMES B. AYER, OF BOSTON.

SECRETARY, DR. JAMES J. POLLOCK, OF CHICAGO.

Neurological Manifestations in Pernicious Anemia; a New Conception Relative to the Etiology.—Dr. A. L. Skoog, of Kansas City, Mo., presented a brief historical sketch of pernicious anemia. Addison, he said, first wrote about the disease in 1849. He then pointed out that pernicious anemia still remained an incurable disease. Possibly more might have been accomplished had we had a better knowledge regarding its causation. Improvement and frequent remissions, sometimes lasting several years, were noted frequently. Where there were definite symptoms on account of an involvement of the spinal cord, brain, and peripheral nerves, the outlook was more serious.

The significance of pernicious anemia in a general way was understood fairly well. Frequent involvement of the nervous system and its importance had not been recognized adequately, but lately there had been much improvement respecting this feature of the malady. The nervous system, he said, was involved in eighty-six per cent. of the cases. There would be found an absence of free hydrochloric acid in at least ninety-eight per cent. A few instances were on record where the acid was absent a number of years before sufficient clinical symptoms appeared to make a positive diagnosis of pernicious anemia. However, it must be remembered that free hydrochloric acid might be absent in individuals seemingly well. The blood picture received earlier and more attention from medical men than the alimentary or neural manifestations. The high color index long had been regarded as a very important diagnostic sign.

Clinical and pathological studies of the neural system would suggest a division into three groups, namely, 1, the spinal cord; 2, the peripheral nerves, and 3, the brain. The first is by far the most important and best known. Various sensory disturbances were among the earliest manifestations. Various degrees of paralyses and disturbances of coordination were frequent. Walking may become impossible.

Spinal cord.—Striking pathological changes in the spinal cord is the rule with a few exceptions. The clinical manifestations may not be explained always by the gross and microscopic findings. There are a few cases on record where the clinical findings indicated an involvement of the cord, but the autopsy revealed no changes. It is difficult to appreciate this discrepancy.

Neuritis.—Some difference of opinion exists relative to the frequency of a true neuritis in pernicious anemia. However, many cases are on record and a few diagnoses have been proved by autopsy. Three years ago the author reported one case from the University of Kansas, where the patient was suffering from a well defined subacute combined degeneration of the spinal cord in pernicious anemia. The clinical findings for a severe parenchymatous neuritis were quite definite.

Psychotic manifestations.—Mild, frequently indescribable, changes in the mental state are noted quite often. A severe or major psychosis appears infrequently. Impaired cerebration with marked memory defect belongs only to the late stage as a rule.

Many infectious diseases including influenza, enteric disorders, typhoid, scarlatina, sprue, malaria, and syphilis have been accused of being the cause of a factor in the etiology.

For a long time our attention has been directed to an intoxication from the lower alimentary tract. Many research workers attribute this to an abnormal flora in the ileum and possibly the duodenum. It has been demonstrated in human beings and in animal experimentation, that if there is no free hydrochloric acid secreted or found in the stomach, quite soon many of the bacteria normally found in the large intestine, such as coli communis, Bacillus Welchii, and streptococci will thrive in the small intestines and even be found in the stomach.

It is desired to offer a theory which could clear up the nature of the cause of pernicious anemia. Attention will be called first to a few salient facts. Pernicious anemia has its onset almost entirely between the ages of forty and sixty. It is practically unknown before the thirty-sixth year. It is considered a chronic and fatal disease. Our observations and records of the earliest stage may be quite deficient. The recorded pathological work deals chiefly with

terminal states. Three great and important anatomical and physiological systems of the body are concerned in the clinical findings and terminal morbid changes; namely, the blood with its hemopoietic organs, alimentary tract with various secreting glands, and the nervous system. All of these organs are the seat of morbid processes during some portion of the course of the illness in more than ninety per cent. of the cases. The initial deviations from the normal may be found in the field of pathological physiology only.

The author said he had arrived at the conclusion that pernicious anemia had its origin in some deviations from the normal originating in the vegetative nervous system. This derangement was purely physiological at its inception and for a certain period following. Attention might be focused on three great vertebral plexuses in the chain of the vegetative nervous system, but an impaired function of the solar plexus should be considered in particular.

One must look further, he said, for operative causes which could produce such profound changes in the vegetative nervous system. Attention was called to the fact that pernicious anemia occurred especially in hypertensive persons among the more highly civilized peoples; that the disease was found among males about three times as frequently as in the female; that it made its appearance almost entirely in the fifth and sixth decades of life. Anxiety and stresses relative to the problems of life, together with this age of declining functions and slow tissue retrogressions, should engage attention. When such conditions had been present over a long period with insidious, slow, continuous insults, there would be registered either physiological or pathological evidence in the three prominent plexuses of the vegetative nervous system. The solar, also designated by the name celiac, epigastric and abdominal aortic, was the major one concerned in this problem. He considered it unnecessary to call attention to a number of brilliant physiological experiments on record wihch showed the effect of emotional states on digestion. Secretions in the stomachs of cats and dogs had been checked completely at any stage by the introduction of factors of great annoyance or fear.

SECTION ON LARYNGOLOGY, OTOLOGY, AND RHINOLOGY

CHAIRMAN, DR. SAMUEL IGLAUER, OF CINCINNATI.
SECRETARY, DR. W. V. MULLIN, OF CLEVELAND.

Maxillary Deformations.—Dr. Harvey Stallard, of San Diego, Cal., spoke on the anatomy of the maxillæ. From a dental point of view the normal complete maxillary structure should have sixteen teeth, each fully developed and in its proper typal place in the skull. There was no fixed size for a normal dental arch nor any definitely determinable curves it should have, but all of its features were dependent upon, 1, the type of the individual and 2, the most favorable environment for full oral development. As the maxillæ develop so grew the visceral portion of the face, but how much the maxilla owed its development to the presence and uses of the teeth no one knew. Fairly well developed faces and jaws sometimes appeared in children lacking nearly all of their permanent teeth. He said one maxilla may be deformed considerably in one or more of its processes or its body, without affecting proportionately as great a deformity in the alveola and palatine processes. The maxillary dental arch can be deformed in three directions according to its three courses of growth: 1, it may be narrowed or it may widen disproportionately; 2, it may be shortened or it may elongate; and 3, it may be prevented from growing downward or it may descend too far. Combinations of these faults, either excessive or diminished growths, produced the great variety of maxillary deformations, usually attended with companion deformities in the mandibles, the nasal cavities, and sometimes even in the orbits. The author discussed the kinds of maxillary deformations referring to two main types: the V shaped and the saddle shaped. Of the latter there were some thirty varieties, depending on the character of the deforming objects exerting the pressure. The V shaped type had fewer variations, owing to the uniformity of the external objects directing their formations. In each kind, the contraction, descent and elongation may be limited chiefly to a half of the face constituting the unilateral type of the deformation. The upper dental arch may be prevented from widening and elongating by external forces causing all the upper teeth to shut inside the lower teeth so characteristic of the contracted-retracted maxillary deformations.

In modern man, only rarely did the upper jaw overdevelop in all three directions, a deformation found in the mandibles of some patients having dwarfed maxillæ. In children or young adults, such deformations were so rare that reports of them have not been clearly recorded, but occasionally individuals were found having expanded and protruded premaxillæ, which were usually accompanied by mandibular retraction. The upper jaw may be shortened and not narrowed, as when the upper anterior teeth and their alveolar processes were pushed backward, so that all the upper teeth bite posterior to normal. Among the causal factors the author spoke of the protoplastic factors and environmental factors, and said that fundamentally heredity is at the basis of all living processes and forms. He also spoke of pressure factors, both prenatal and postnatal; functional pressures; perverted respiratory and masticatory functions; deglutitory perversions, which affect the positions of the teeth, were those manifested in the tongue and cheeks during swallowing.

The theory of lack of pressure was also taken up at some length. Referring to the related nasal deformations accompanying maxillary contractions, the author said that since the exactitude of occlusion was so definite it taught him the importance of external pressure, and he surmised that some of such undoubtedly affected the shape and volume of the nose. It would only be natural to conclude that any pressure constricting the maxillary apparatus would narrow the nasal cavities. In conclusion, the author suggested that a study of nontraumatic septal deviations and asymmetrical noses be made in young adults, comparing them with the malocclusions and the postural habits of the individuals. A study should be made of the size, health and drainage of the sinuses, particularly the maxillary, in connection with the asymmetrical forms of malocclusion and their corresponding pillow habits, using the more normal sides as cheeks. The proposed study, at least,

seems promising, the author said, and would be, to the common facial deformations, an approach similar to that made by physicians in their study of deformations elsewhere in the body, particularly in the cranium, chest, spine and shoulders.

Injected Iodized Oil in the Röntgen Ray Diagnosis of Tracheal and Bronchopulmonary Conditions.—Dr. Samuel Iglauer, of Cincinnati, Ohio, in his chairman's address, said that Jackson was the first to introduce radiopaque substances into the bronchial tree as an aid to x ray diagnosis. For this purpose he insufflated dry bismuth through the bronchoscope. Lynah and Stewart, in 1918, for the first time injected a fluid substance as a contrast medium. The fluid substance consisted of bismuth suspended in olive oil. They obtained excellent röntgenograms of lung abscesses and also noted some therapeutic effects from the bismuth. Sicard and Forestier, in 1922, reported on the use of iodized oil, lipiodol, forty per cent. iodine content, which after injection into the bronchial tree gave remarkable outlines of pulmonary lesions. DeLille, by this method, was able to detect bronchiectatic lesions in children who were housed in a tuberculosis sanatorium, under the mistaken diagnosis of tuberculosis. The French school introduced lipiodol either with a long laryngeal syringe or through a puncture through the cricothyroid membrane. In the United States, Clerf and Ballon have used the bronchoscope. The bronchoscopic method is the most certain but not universally applicable. The Austrian school introduced iodipin which they have substituted for lipiodol, through a retention catheter passed through the glottis. Nather cocainized the pharynx and larynx and states that the patient will then swallow the oil into the trachea.

Introduction of oils is a laryngological problem. The laryngeal syringe demands considerable skill on the part of the physician. Puncture through the cricothyroid space is not certain and at times the oil is injected into the peritracheal tissues. The bronchoscopic method is the most certain, but not universally applicable. The laryngeal catheter requires considerable cooperation on the part of the patient.

The author has devised a new method which consists in the introduction of a specially devised double barrelled intubation tube, i. e., an intubation cannula. A rubber tube is connected with one barrel. After cocainizing the larynx the intubation tube is introduced and the iodized oil is injected through the rubber tubing, which projects from the patient's mouth. The second barrel of the intubation tube permits the patient to breathe while the oil is being injected. The whole procedure may be carried out under the fluoroscope and is applicable to children as well as adults. By placing the patient in any desired position the flow of the oil may be directed into the dependent portion of the lung. The author has also devised a new method of demonstrating subglottic stenosis of the larynx. A finger cot filled with a radiopaque fluid is pulled into the larynx above the tracheal cannula, which the patients usually wear. A röntgenogram is then taken showing the extent of the stenotic area in the larynx. In conjunction with Samuel Brown, George Benzing and Warren C. Breidenbach, the author has examined a series of lung conditions, including cases of bronchiectasis, lung tumors, pulmonary tuberculosis, collapse lungs and pulmonary abscesses. The method is particularly valuable in the study of bronchiectatic cavities and is also of value in the study of the other diseases mentioned. The intubation method described appears to be the simplest method yet devised for the introduction of contrast substances.

SECTION ON DERMATOLOGY AND SYPHILOLOGY

CHAIRMAN, DR. FRED WISE, OF NEW YORK.

SECRETARY, DR. JAMES H. MITCHELL, OF CHICAGO.

A Distinctive and Severe Form of Erysipeloid Among Fish Handlers.—Dr. Joseph V. Klauder, Dr. Linwood L. Righter, and Dr. Malcolm J. Harkins, of Philadelphia, said that the skin disease which Rosenbach designated as erysipeloid was now definitely established as an infection with a human strain of the bacillus of swine erysipelas. This disease was one form, a mild one, of erysipeloid. The clinical symptoms of this disease were discussed. Subsequent observations disclosed another form, a severe one, of erysipeloid, due to infection with a swine strain of the bacillus of swine erysipelas most frequently seen in veterinarians and laboratory workers accidentally inoculated with culture of such organism and in butchers, farmers, meat inspectors infected through handling diseased pork. The clinical symptoms of this form of erysipeloid were much more severe than the mild form; moreover, lymphangitis, adenitis and extension of the disease above the wrist was frequent.

This report was based upon a study of about one thousand cases of erysipeloid among commercial fishermen working in fish ponds along the northern New Jersey seacoast. The disease commonly appeared on the hands at the site of trauma caused by the bite of fish, or the prick of the scales, spines or fin of fish. It was intimately associated with the handling of slimy, spiny fish. It also appeared on various parts of the body at the site of trauma inflicted through soiled fishing clothes. The symptoms were those of erysipeloid, the severity of which approached the picture of swine erysipelas in man. In addition, constitutional symptoms were common. Acute cases have been observed. Factors which determine incidence of the disease and the geographical distribution of the infection among fishermen was discussed. It appeared that the disease was prevalent among commercial fishermen in all parts of the world. The infection as an occupational disease was discussed. From replies to a canvass by mail of many commercial fisheries handling live fish, fish shipped to the market and canners of fish, it was apparent that the disease was an important one of the fishing industry and known in these circles as fish poisoning. In personal studies the infection was the chief cause of disability among commercial fishermen handling live fish. It appeared that the infection from handling fish shipped to the market was milder, conforming clinically to the mild form of erysipeloid.

The universal dissemination of the bacillus of swine erysipelas and its habitat in dead matter of

animal and plant origin was discussed, and the different animal strains of the organism were discussed. Differences in the symptomatology of the infection in man could be accounted for by differences in the virulence of the organism, depending upon the source of infection.

From patients presenting the reported type of erysipeloid, the bacillus of swine erysipelas was recovered by culturing an excised piece of the involved skin. Bacteriological studies were reported. The organism was highly virulent to pigeons and to white mice in the smallest amount injected—.0003 c.c.

The author said that agglutination and complement fixation studies were also conducted. Unsuccessful attempts were made to demonstrate the bacillus of swine erysipelas in bacteriological studies of fish slime. The foregoing studies suggested a fish strain of the bacillus of swine erysipelas. From the strain or organism recovered, a serum was being prepared for treatment. Local treatment of the infection was of little value since it apparently does not shorten the period of disability, which ranged from two to six weeks. The treatment of erysipeloid with the serum of swine erysipelas as reported in the German literature was discussed. Such treatment was considered very effective.

SECTION ON OPHTHALMOLOGY

CHAIRMAN, DR. ARNOLD KNAPP, OF NEW YORK.

SECRETARY, DR. WILLIAM C. FENNOFF, OF DENVER.

The Prostate as a Remote Focus of Infection in Ocular Inflammations.—Dr. William Zentmayer, of Philadelphia, Pa., said that attention is called anew to the importance of searching further than the nose, mouth and throat for the portal of infection in ocular inflammations and emphasis laid on the fact that this is not infrequently found in the prostate. He gave a summary of de Schweinitz's elaborate thesis on the relation of metastatic inflammations of the eye.

Histories of four cases were given in which in all probability the source of infection was the prostate gland. The first was a case of uveitis undoubtedly due to a focus of infection in the prostate, of gonococcal origin, and in which the infection lost its specificity probably under treatment with gonococcal vaccines. This conclusion is strengthened by the fact that after the prostatic condition cleared up there was no recurrence of the ocular inflammation. It illustrates the persistence over many years of the gonococci in the genitourinary tract, and their menace as a metastatic agent. The second case was one of iritis in which the etiological factor was a focal infection originating in the genitourinary tract, apparently in the prostate. In this and in the former case a severe exacerbation of the ocular inflammation resulted from massage of the prostate. The third case would fall in the class in which there are several possible portals of infection. Inasmuch however as attacks occurred after the removal of two which were eradicable, and there was a prostatic infection with positive gonococcal complement fixation, it is highly probable that the etiological factor here was the prostatic trouble. The fourth case was one of central exudative retinochoroiditis where the physical and laboratory examinations were negative except for a moderate von Pirquet reaction and very evident prostatic infection, in which after a long period of quiescence a fresh attack of retinochoroiditis followed one month after a second attack of gonorrhea.

The paper also contains the views of Dr. B. A. Thomas concerning the prostate as a source of infection. The following conclusions are given:

1. The prostate may be the source of infection in certain ocular inflammations. 2. The prostatic inflammation is probably more often nongonococcal than gonococcal. 3. The metastasis, as in other focal infections, may be to any of the ocular tissues susceptible of inflammatory reaction, but the uvea and cornea are probably most often involved; the latter, and also the iris alone, especially when the gonococcus is present. 4. The fact that an inflammation persists after the removal of a suspected focus of infection does not prove that this was not the primary source of infection as the resistance of the tissues may have been so reduced by this inflammation as not to be able to withstand the action of the organisms or toxines of a much less virulence from some other part of the body. 5. Only when a metastatic inflammation subsides after the removal of one possible source of infection does it prove this to have been the excitor.

Tolerance of Foreign Bodies in the Posterior Segment of the Eyeball.—Dr. Albert E. Bulson, Jr., of Fort Wayne, Indiana, pointed out that while in the great majority of instances foreign bodies which penetrate into the interior of the eye entail its ruin and too frequently even that of its fellow, they occasionally are met with situated harmlessly in every part of the globe. He gave a short history of thirty-five cases reported in the literature in which foreign bodies have lain innocently in the posterior segment of the eye for a considerable time without serious results, and in not a few instances with no impairment of central vision. He quoted Hermann Knapp (*Archives of Ophthalmology,* 11; 222; 1882) to the effect that we should not forget that toleration even if once established, was not illimited, as the foreign body after any number of years might become loose and produce irritation, or without coming loose may produce repeated attacks of internal inflammation. He also quoted Adams (*Transactions of the Ophthalmological Society of the United Kingdom* 3:115:1883) to the effect that such cases as reported could not fail to compel us to reflect whether we have not in times past been somewhat hasty in advising enucleation, and possibly too energetic in endeavoring to extract foreign bodies.

After the röntgen ray came into use, it became practically universal to locate foreign bodies within the eye by their aid, and if the foreign bodies could not be withdrawn by magnet, the eye was enucleated. In consequence, very few cases had been reported within the last few years in which foreign bodies had been retained within the eye.

For the purpose of adding to the number of cases on record, Dr. Bulson reported three cases. In the first case, a piece of iron penetrated the eyeball and lodged on the retina where it remained during the ten years that the patient was under observation, without serious disturbance, though when the patient was

last seen he had a cataractous lens. In the second case, a piece of steel penetrated the eyeball and lodged in the retina, where it could be seen plainly by ophthalmoscopic examination over a year later. The eye was perfectly quiet and central vision was normal with correcting lenses, and the field of vision was normal except for a large scotoma marking the site of the foreign body. In the third case a piece of steel penetrated the eyeball and remained for a year before creating a disturbance, and enucleation became necessary.

Numerous authors were quoted to the effect that the earliest possible removal of the foreign body was the first thing to be considered, and that it usually should be done at any cost, even to the removal of the eye, but he pointed out that even after the successful extraction of a foreign body, the safety of the eye was not assured. For the majority of the cases useful vision would be lost, and the injured eye would have to be sacrificed for the safety of the other. Though the eye seems to do well for a time, it may become the seat of a slow uveitis that after weeks or months will destroy it. Admitting that while foreign bodies may lie in the background of the eye for long periods of time, even with the retention of good vision, and that they never can be trusted owing to the fact that they are liable to cause inflammatory and degenerative changes, yet the argument is advanced that many of these cases are just as well off if a waiting policy is pursued, providing the case is kept under observation so that with the first indication of trouble enucleation or other appropriate attention can be instituted. The author quotes Beard (*Ophthalmic Surgery,* 1910, page 622) who offers some rules of guidance for intervention and abstention.

The author's final conclusions are as follows:

1. It is assumed that in the majority of cases, loss of vision as well as loss of the eyeball is due to inflammatory, degenerative and structural changes brought about directly or indirectly by the trauma and infection, and not to the mere presence of a foreign body in the posterior segment of the eye, and that the removal of the foreign body does not in itself improve the prognosis, as it is probable that the ultimate loss of vision or eyeball, or both, in a series of comparative cases, would be as conspicuous in cases in which extraction had been performed as it would be in those in which extraction had *not* been performed.

2. In a large percentage of cases the patient is as well off if the foreign body is left in the posterior segment of the eye as he would be if it is extracted, particularly if the eye traumatism would be increased by the extraction, and for the following reasons:

a. Even if the foreign body is removed successfully there is no assurance that the eye, sooner or later, may not become the seat of inflammatory and degenerative changes that may destroy sight and perhaps require enucleation. Furthermore, the effort at removal may do more damage to sight and the integrity of the eye than would be the case if there had been no intervention.

b. If sepsis has been introduced, or iridocyclitis has set in, the prognosis is as good with the foreign body in the eye as with it out, for in either case enucleation would be adopted if the process did not yield with reasonable promptness to appropriate treatment. It is entirely problematical whether or not the foreign body in the posterior segment of the eye in itself would in any way alter the course of the inflammation. Perhaps copper may be taken as an exception.

3. The cases herein reported, and many more of a similar nature that probably could be obtained, indicate that preservation of useful and even fairly normal vision, or eyeball, or both, is possible for prolonged periods of time, perhaps during the lifetime of the patient, with retention of a foreign body in the posterior segment of the eye, and it is justifiable to assume that these patients would not have fared any better nor would it have been any safer had intervention been adopted at any time in the course of any of the cases.

4. Every case is a law unto itself, but most of our teaching concerning the subject under discussion has been toward too much radicalism in electing intervention in foreign body cases. The plea therefore is made that there should be less haste in advising enucleation, and less general inclination to be energetic in endeavors to extract foreign bodies from the posterior segment of the eye. More time and thought should be given to an analysis of the conditions presented in each individual case, and the possibilities that may follow intervention and nonintervention. Furthermore, more time and care should be given treatment. The danger of sympathetic inflammation in the average perforating injury with retention of a foreign body in the eye is as great after the foreign body has been removed as it was before, and in either case the well trained oculist will recognize the time for the cessation of conservatism.

5. Foreign body cases of the type under discussion, whether the foreign body is removed or not, potentially are dangerous throughout the life of the patient, and the patient should be so advised in order to be on his guard and ready to consult a competent ophthalmologist at the first indication of trouble. His best interests are not conserved by the ultraradicalism advocated by some of our ophthalmological writers.

Mucous Membrane from the Middle Turbinate in Plastic Surgery of the Eye.—Dr. Meyer Wiener, of St. Louis, Mo., said that providing sufficient mucous surface for covering defects of the conjunctiva can be readily secured without harm to the patient, its advantages over skin grafts must be admitted. Skin, especially in symblepharon, is unsightly, rough, exfoliates, often gives off unpleasant odor with discharge, and always retains the general characteristics of skin. Mucous membrane has all of the advantages of skin with none of its disadvantages. The difficulty heretofore has been to obtain enough mucous membrane from the host, to supply the conjunctival defect, without seriously inconveniencing the patient. This has been accomplished by utilizing the mucous membrane carefully dissected off of the patient's middle turbinate after its removal. Naturally this can only be done with adults, unless the mucous membrane is taken from an individual other than the one to be grafted, which has not yet been tried. The transplanted mucous membrane, which at first is quite thick, gradually becomes thinner and more closely assumes the features of the conjunctival mucous membrane. No disadvantage has resulted to any of the patients operated upon from their loss of the middle turbinate.

Abstracts from Current Literature

ENDOCRINOLOGY

Otorhinolaryngological Symptoms of Incipient Basedow's Disease.—J. Erath (*Revue Française d'Endocrinologie,* March-April, 1925) describes this form as occurring frequently in Switzerland after the use of iodine preparations for the treatment of goitre. Among these symptoms are aphonia with tremor of the larynx, a sensation of constriction at the throat, a small goitre, paroxysmal rhinorrhea, frontoorbital neuralgia, subjective noises in the ears with normal hearing, hyperesthesia of the labyrinth, and the various symptoms of cardiovascular erethism encountered in Basedow's disease.

Pathogeny of Ozena as a Sympathetic Endocrine Disturbance.—In nearly all the cases of ozena examined by E. Halphen and R. Schulmann (*Revue Française d'Endocrinologie,* March-April, 1925) thyroid, ovarian, or sympathetic disturbances were found, such as acrocyanosis, chilblains, hot flashes, mydriasis, reversal of the oculocardiac index. The thyroid body was almost always hypertrophied, menstruation always irregular, but the results of the "biological tests" with adrenalin and pituitary extract were never demonstrative. On the contrary, injection of adrenalin invariably produced diminution or disappearance of the crusts and the evil odor. The authors conclude that the sympathetic is the system chiefly affected in ozena. This affection then would be due to a disturbance of the sphenopalatine branch, provoked by a lesion of the endocrine glands, in its turn due perhaps to syphilis or tuberculosis.

Goitre Incidence in School Girls of New York City.—I. H. Goldberger and A. K. Aldinger (*American Journal of Diseases of Children,* June, 1925) found that a definite thyroid incidence exists among the school children in certain localities of the United States, known as goitre belts. Goitrous regions are identified as localities deficient in iodine content of the water supply, salt and air. Simple goitre is a disease of iodine starvation and is evidenced by an enlargement of the thyroid gland. It is more prevalent in girls than in boys. The etiology of goitre is unknown, although it is known to develop when the iodine content of the thyroid gland falls below 0.1 per cent. of the total dried substance of the gland. Thyroid enlargements make their appearance at four periods of life: Fetal, adolescence, during pregnancy and at the menopause. Simple goitre is a compensatory hyperplasia of the thyroid gland, developing during the course of certain metabolic disturbances of unknown origin, but immediately dependent on a relative or on an absolute deficiency of iodine. The latter exercises both a prophylactic and a curative effect on simple goitres.

The authors' study disclosed that enlarged thyroids were most prevalent between the ages of thirteen and fifteen years. The greatest incidence of thyroid enlargement was in the slightly enlarged group, 17.2 per cent; moderately enlarged, 2.6 per cent; markedly enlarged, 0.5 per cent.; total 20.3 per cent. Thyroid enlargement in colored children is approximately seven per cent. less frequent than in the white children in this study. Some observers state that a racial immunity to endemic goitre exists. Although this study suggests that the percentage of incidence of normal glands seems to vary inversely with the activity of the menstrual cycle, the findings should not be construed as conclusive. A distinct relationship exists between thyroid incidence and such signs as tremor, mottling and exophthalmos. Girls whose mothers were of foreign birth showed the least incidence to thyroid enlargement.

Thermogenesis as the Fundamental Function of the Adrenal Medulla and Cortex.—Personal study and much evidence in the studies of others convince C. E. de M. Sajous (*Endocrinology,* November-December, 1925), that cholesterol is the systemic antithermic through its established property as an antihemolytic in inhibiting the thermogenic function of oxidized lecithin. He believes that the adrenals synthetize adrenoxin, lecithin, and cholesterol. The red corpuscles while passing through them appropriate these thermogenic agents and, after passing through the lungs to have their adrenoxin take up oxygen from the air, proceed to the tissue cells. There is thus a chain of structures in physiological sequence, the adrenals, the red corpuscles, the blood platelets, and the tissue cells, which all contain the same thermogenic agents, with the adrenals as synthetic organs acting as source of supply. The secretion of the thyroid gland is the antagonist of cholesterol in thermogenesis; it increases the lability or sensitiveness of the lecithin phosphorus to oxidation, and thus enhances thermogenesis correspondingly. This oxidation of the phosphorus in lecithen by the oxygen of the adrenoxidase it is which sustains tissue respiration.

The Influence of Desiccated Spleen and Bone Marrow Feedings Upon the Erythrocyte and Hemoglobin Contents of the Blood.—S. Shapiro and F. H. Frankel (*Endocrinology,* November-December, 1925) administered to a series of quiescent hospital patients five grains each three times a day of desiccated spleen and bone marrow. Blood counts were made three times a week. In alternating periods of about a month in duration the feedings were given and withheld. During the periods of feeding there occurred increases in the erythrocyte and hemoglobin contents of the blood, which returned to about the prefeeding level when the preparation was withheld.

Röntgentherapy of Pituitary Tumors.—Herrnheiser (*Fortschritte auf dem Gebiete der Röntgenstrahlen,* April, 1925) reports two cases. The first was of acromegaly of two years' standing in a woman thirty-two years old, presenting the typical clinical picture of the disease. In the röntgenogram the sella appeared much enlarged and destroyed. The patient had headache constantly increasing in severity and marked disturbance of vision. From the time of the first irradiation she experienced improvement, and finally attained complete freedom from headache, arrest of the acromegalic process, and subjective well being. The second case was that of a twenty-four year old man with the typical picture of genitocerebral dystrophy with pituitary dwarfism. Röntgenologically the sella was greatly enlarged and destroyed, and lime deposits were seen in the tumor. The patient gave unmistakable evidence of brain pressure in intense headaches, vomiting, and disturbances of vision. Five weeks after the first raying the eyesight and headaches were greatly improved. In the first case four fields, in the second three were rayed, each receiving eight Holzknecht units, 180 kilovolts at forty centimetres focal distance through half a centimetre of copper and one of aluminum. In another case of acromegaly, irradiated to the limit, no improvement took place. The result depends on the radiosensitiveness of the tumor, which is very variable. Overdosing may do great harm. The author advises beginning with very mild doses and increasing them as indicated.

Heart in Hyperthyroidism.—V. J. Thacker (*Medical Clinics of North America,* January, 1926) remarks that as to the incidence of definite cardiac damage in hyperthyroidism, twenty-five per cent. would be an average figure with severe cardiac damage in from two to six per cent., depending on the various series of cases considered.

In reference to the origin and reduction of cardiac damage in this disease the old mechanical pressure theory is no longer tenable. The toxic theory has been coming into favor, as it is the only theory that adequately explains all the cardiac phenomena occurring, as observed clinically as well as at necropsy. However, most observers consider the mechanical theory of increased metabolism, necessitating increased cardiac work, an important factor, making the heart more susceptible to the thyrotoxic influence, this toxin arising from the thyroid gland, being either an increased secretion of thyroxin, an altered secretion, or both.

The steps in the production of cardiac damage are apparently as follows: Increased metabolism, increasing cardiac work as shown by tachycardia and increased output of blood; fatigue results and leads to hypertrophy and attendant dilatation and atony. The toxic action comes into play, leading to degeneration in susceptible hearts. In time cardiac damage manifests itself by further dilatation and hypertrophy and even heart failure without arrhythmia, or much more frequently arrhythmia, usually auricular fibrillation, occurs usually with heart failure, most commonly of the congestive type.

The actual pathology found at necropsy seems to confirm the toxic theory, since degenerative and nonsuppurative in-

flammatory lesions are rather constantly found and reported by various investigators.

Of the special disorders of the heart, auricular fibrillation is essentially the only important arrhythmia found. The constancy with which it is found in damaged hearts is striking. It usually means, when of the established type, that the heart is rather seriously involved. Practically all cases of heart failure show it. Paroxysmal fibrillation is not as serious, but usually precedes the established type. Auricular fibrillation, then, generally means that the heart is definitely damaged and failing. Furthermore, its presence further decreases cardiac efficiency and increases the strain on it, thus favoring further heart failure. In its production long duration of hyperthyroidism seems to predispose, as the incidence increases with age, and after fifty years of age fibrillation is an almost constant accompaniment of heart damage.

Other cardiac disorders are of minor importance and not characteristic or frequent.

Cardiac enlargement is present constantly in damaged hearts, both dilatation and varying degrees of hypertrophy accounting for it. Murmurs systolic in time occur, but are not diagnostic and are not due to valvular disease in uncomplicated cases, but to left ventricular dilation with a relative valvular insufficiency.

Longstanding Hyperthyroidism with Spontaneous Subsidence.—C. L. Eshleman (*Medical Clinics of North America,* January, 1926) reports a case in which the toxic symptoms associated with the thyroid dysfunction were prominent and serious from 1903 to 1916. During the next two years these symptoms began to abate, and the patient gained much in weight with gradual diminution in the size of the gland, until at the time of writing the case was really no longer a toxic thyroid, but merely a case of myocarditis, with the patient able to carry on, but with greatly diminished activity. This is merely the residual damage of many years of thyroid intoxication, and the patient is now, at fifty-seven years, a chronic cardiac case.

This case brings to mind certain facts: 1. Some thyrotoxic patients become quiescent and spontaneous subsidence of toxicity occurs, which cannot be directly attributed to any special treatment. 2. Not infrequently this occurs in mild cases, in the severe typical Graves' disease rarely. 3. Complete disappearance of all signs of enlarged thyroid can occur. 4. The opposite condition of myxedema may develop in later years. 5. The residual effects of chronic hyperthyroidism manifest themselves chiefly in damage to the heart muscle, usually considered to be a toxic myocarditis. 6. Where spontaneous or surgical recovery occurs, the extent of myocardial damage largely determines the patient's future activity. 7. Any prolonged postponement of surgical measures is likely to result in permanent myocardial damage.

Postoperative Thyroid Reaction.—L. F. Sise (*Surgery, Gynecology and Obstetrics,* July, 1925) reports that in the great majority of toxic thyroid patients, under nitrous oxide oxygen anesthesia, with the technic used in this clinic, a postoperative reaction is indicated, roughly proportionate to the increase above normal in pulse rate, pulse pressure, systolic blood pressure, and respiration. In a small group of patients the disease has apparently progressed beyond the condition in which this is true. With them the postoperative reaction and especially the postoperative mortality is roughly in inverse proportion to the increase in the pulse rate, pulse pressure, systolic blood pressure and respiration. This small group is asthenic and apathetic and their operative mortality is high.

A much more accurate forecast of the postoperative reaction of toxic thyroid patients can be made by taking into account both the preoperative condition of the patient and the course of the anesthesia than can be obtained from either of these procedures alone.

Reidel's Chronic Thyroiditis.—A. F. B. Shaw and R. P. Smith (*British Journal of Surgery,* July, 1925) say from a study of the literature and their own cases that they have been unable to collect any evidence that the condition is an involution following a previous goitre. In a few cases there has been a history of goitre or Graves' disease in other members of the family. They believe that the disease is a chronic inflammatory process of a granulomatous nature, and this view receives ample support from its clinical characters and the anatomical changes in the gland.

As to the relation, if any, between Riedel's struma and fibrous atrophy of the adrenals, the authors were unable to express an opinion, except to say that the anatomical changes were strikingly similar. That the alterations in the thyroid in their case are not the result of some disturbance in the gland following adrenal disease seems to be proved by Huebschmann's observation that in fibroid atrophy of the adrenals the thyroid is normal. At any rate their case suggests the possibility that the factor responsible for Riedel's struma may also attack other members of the endocrine glands.

A Case of Tetania Parathyreopriva Treated with Collip's Parathyroid Extract.—H. Lisser and H. C. Shepardson (*Endocrinology,* September-October, 1925) maintain that they were the first to treat a case of tetania parathyreopriva with Collip's hormone. A detailed account is given of the progress of the treatment, which was tentative at first in the absence of criteria as to doses under such circumstances. Diagnosis was established three weeks after operation for goitre on finding three normal parathyroid glands in the mass of excised tissue. Blood calcium estimations were constantly made, the amount fluctuating with the amount of hormone administered or with its withdrawal between 7.2 and 11.9 milligrams to the hundred cubic centimetres of blood. The patient continued the injection of the remedy after her discharge from the hospital, examining her own blood, much as does a diabetic patient with insulin.

Hypopituitarism and Diabetes.—In five cases of hypopituitary disease H. J. John (*Endocrinology,* September-October, 1925) found decreased carbohydrate tolerance, although no glycosuria was present in any instance. One case was definitely diabetes, one a mild type of diabetes, and three patients were in a prediabetic stage. All patients were obese.

Geographical Distribution of Epilepsy and Endemic Goitre in Switzerland.—V. M. Buscaino says (*Rivista di Patologia Nervosa e Mentale,* March-April, 1925) that in Italy, the United States, and Switzerland epileptics are especially numerous in regions where epidemic goitre prevails. In Italy and the United States they are numerous particularly near the seacoast. In other words, epilepsy is most frequent in all three countries in regions where the thyroid gland functions very actively or incompletely, or in localities abounding in iodine (brisk thyroid function at the seashore) or deficient but not exceedingly deficient in that element. These facts support the dysthyroid anaphylactic theory of epilepsy.

The Diagnostic Criteria of Chronic Parathyroid Insufficiency, With Special Reference to the Phosphate Content of the Blood.—Louis Berman (*American Journal of the Medical Sciences,* February, 1926) gives as the criteria which may be used in the diagnosis of chronic parathyroid insufficiency and in gauging the effect of treatment. 1, dystrophies of the hair, nails, teeth and skin; 2, mechanical hyperexcitability of the nerves; 3, electrical hyperirritability of the peripheral nerves; 4, dimished calcium content of the blood, negative calcium balance; 5, decreased phosphate content of the urine, phosphate retention in tissues increased phosphate content of the blood.

Prognosis in Exophthalmic Goitre.—J. Marion Read (*American Journal of the Medical Sciences,* February, 1926) says that acute cases of exophthalmic goitre with well defined onset offer a more favorable prognosis than those with insidious onset and long existing symptoms. The height of the metabolic rate offers only slight assistance in estimating the prognosis. Males seem to be more resistant to treatment and are more apt to become chronic sufferers than females. Subtotal thyroidectomy nearly always produces a remission of the disease if the patient survives the operation, but it does not constitute a cure.

Heterotopia of Adrenal in Liver and Kidney.—Carl Vernon Weller (*American Journal of the Medical Sciences,* May, 1925) understands by heterotopia of the adrenal in liver and kidney the developmental inclusion of the adrenal in or beneath the capsule of one of these organs. Inflammatory adhesions and the lesser aberrant adrenal masses are not included in this definition. Duplication of the adrenal may be present.

Of adrenal renal heterotopia one new case is added. This condition occurs chiefly in males and is usually bilateral.

Three new cases of adrenal hepatic heterotopia are added. Although presumably the more common of the two, this has received but little mention in the literature.

Adrenal heterotopia is usually associated with a persistent thymus and other evidences of the thymicolympathic constitution, and frequently with the asthenic habitus. It is an

evidence of constitutional pathology. Two patients in the thirteen cases reported died of diabetes. In accord with what is known of this constitution, in most cases of adrenal heterotopia the patients have died at a relatively early age. The incidence of tuberculosis and other infections is high.

In adrenal renal heterotopia the surgeon will inevitably remove the adrenal in doing a nephrectomy unless special precautions are taken. Due to the medullar hypoplasia usually present and the bilateral nature of this condition, it may be especially important that the heterotopic adrenal should not be removed.

Relation of Thyroid Secretion to Specific Dynamic Action.—Emil J. Baumann and Louise Hunt (*Journal of Biological Chemistry,* July, 1925) states that complete thyroidectomy caused a gradual decrease and final disappearance of specific dynamic action after about sixty-five days. Restoration of this action which had completely disappeared following thyroid removal was accomplished by feeding thyroid gland. Incomplete thyroidectomy caused a decrease of specific dynamic action, which would be increased again by feeding thyroid and in some cases of feeding a small amount of potassium iodide.

A Pure Strain of Thyroid Cells and Its Characteristics.—Albert H. Ebeling (*Journal of Experimental Medicine,* March, 1925) describes in full the technic used in the isolation and maintenance of a strain of thyroid cell, and the cultural properties of the thyroid cells. Their multiplication *in vitro* was observed for seven months, and it was as active at the end of this time as at the beginning, and the cells had retained their individual characteristics. Embryonic tissue juice must be present in the culture medium for indefinite multiplication. The thyroid cells grow at the surface of the coagulum as pavement epithelium, and within the coagulum as a glandular structure. The cells did not dedifferentiate, and the lumen of the acini in cultures from a strain over four months old contained colloid secretion similar morphologically to that from a freshly extirpated thyroid gland. The study of the endocrine glands by the method of tissue culture thus appears to be practicable.

BLOOD AND LYMPH GLANDS

Sickle Cell Anemia.—Earl Z. Browne (*Medical Clinics of North America,* January, 1926) states that sickle cell anemia is probably a familial and hereditary defect of the spleen and the blood forming organs, with a resulting change in erythrocytes which predisposes to hemolysis and phagocytosis. The anemia is the result of excessive blood destruction, activated by factors that would be innocuous in a normal person. The increased indirect van den Bergh reading that is present supports this view of a hemolytic process. In histological studies the spleen appears packed with red blood cells, more in the spaces of the pulp than in the sinuses. Fibrosis is also present and large focal deposits of iron free pigment. The elastic tissues of many of the splenic arterioles give the iron reaction. Pigment is also present in excess in the liver, both in the hepatic and Kupfer cells, and can always be found in the endothelium of the capillaries of various organs; in the collecting tubules of the kidneys and in the glomeruli as well. The destruction of red blood cells is most pronounced in the spleen. No iron pigment is found in the bone marrow. Just what the toxin is we do not know.

The treatment of these cases, as of the primary anemias in general, is notoriously unsatisfactory. Various remedies have been tried, mainly iron and arsenical preparations, rest in bed, plenty of fresh air and sunshine, and frequent small transfusions of blood, the latter being of more use than anything else tried.

The outlook is bad, the course being gradually a downward one, and the curtain is generally rung down by an intercurrent disease. It has been stated that these patients rarely live beyond the age of thirty years.

Difficulties in the Diagnosis of Leucemia.—G. Lovell Gulland (*British Medical Journal,* July 18, 1925) regards leucemia as "a sarcoma of the leucocytes." The assumption of a sarcomatosis, however, does not settle the question, as the problem is bound up with the question of what influence it is which in health keeps the normal number of leucocytes in the blood within such narrow limits. We know that the action of parasites (bacterial and other organisms) can powerfully alter the count in disease in both positive and negative directions, that the proteins of food and probably other proteins and many other substances have definite actions. Does the interaction of an infinite variety of substances keep the balance in health, and, if so, does it act directly on the bone marrow and the blood, or through the medium of some other organ? These questions require a definite answer before we shall progress much further in the understanding of leucocyte problems.

It is very striking when one examines the marrow of a myeloblastemic patient who has died with a count of, say, 20,000, to find all the tissues packed with myeloblasts, to the practical exclusion of every other type of cell. The wonder is, not that the leucocyte count is increased, but that it is not vastly higher. One cannot resist the feeling that the excess of cells in the blood is there rather as an overflow than in a response to any active call upon the marrow cells. Obviously the condition is widely present in the marrow before there is any evidence in the blood of its existence. A leucocytosis responding to an organismal infection occurs practically at once, and the marrow gets under way immediately, but never goes beyond the amount of hypertrophy required in each special instance. A leucemia progresses in the marrow more or less steadily, in the acute cases progressively till death occurs. We do not know whether the spontaneous remissions which sometimes occur in the blood picture of the chronic leucemias correspond to a real alteration in the condition of the marrow; if they do they are not more frequent than the retrogressive changes that occur in some tumors. It is well to keep an open mind, but until further research throws fresh light on the disease the neoplastic theory of its causation is the most logical and satisfying explanation.

Clinical Value of the Van den Bergh Reaction for Bilirubin in the Blood.—J. W. McNee and Chester S. Keefer (*British Medical Journal,* July 11, 1925) assert that the Van den Bergh reaction is the best method so far available for the clinical investigation of the bilirubin content of blood serum or plasma. It has numerous advantages over other tests which have subsequently been proposed; 1, its extreme delicacy; 2, it is not given by other yellow substances which may color the plasma; 3, it gives important qualitative distinctions between certain forms of icterus; 4, it can now be used for a satisfactory quantitative estimation of bilirubin.

The qualitative reaction may enable a postitive diagnosis of obstructive or of hemolytic jaundice to be made. Pernicious anemia, except in the stage of rapid temporary improvement, can be distinguished from secondary anemias. In some diseases (for example, catarrhal jaundice, subacute liver atrophy, cardiac failure) the reaction may pass through all the stages from completely delayed to prompt direct, as the disease progresses. As a rule, however, in the commonest type of jaundice (the toxic and infective hepatic group) no information of any diagnostic or prognostic value is given to the clinician. The test, however, is of great practical value for the detection of socalled latent jaundice.

Blood Transfusion.—A. O. Bryan (*New Orleans Medical and Surgical Journal,* December, 1925) maintains that there should be no reason for a patient's dying of acute hemorrhage for lack of blood. Each donor should correspond in group with the recipient, and in addition should be cross agglutinated just before transfusion. Citrated blood is contraindicated in cases of lengthened coagulation time and low platelet counts. There are very few severe reactions from transfusion in secondary anemias, and one gets greater success in these. In primary anemias transfusion should be given as often as five days and in small amounts, in order to prevent a fall in the hemoglobin curve, and after the hemoglobin has been raised to eighty per cent. this should be maintained by injection of whole blood subcutaneously. He also asserts that blood transfusion is a specific for purpura hemorrhagica.

Transfusions of Plethoric Blood in Pernicious Anemia. P. Emile-Weil and R. Stieffel (*Bulletins et mémories de la Société médicale des hôpitaux de Paris,* November 26, 1925) state that in pernicious anemia transfusion acts not only by replacing plasma and red cells but, in particular, as a powerful stimulant to the hematopoietic organs. Out of twelve cases treated with ordinary blood three were cured, six showed prolonged improvement and three were uninfluenced. The reasons for the failure in the latter had been thought to lie in some serious organic disorder, such as neoplasm, or in a complete annihilation of the hematopoietic organs which precluded restoration of their function. Experience with a recent case, however, showed that the difficulty may consist in the use of an unsuitable type of blood for the

transfusion. In a woman of fifty years, anemic since childhood, and with one million red cells and twenty-five per cent. of hemoglobin, four transfusions of ordinary blood in the course of six weeks caused only a slight, transient improvement, the condition being worse after the fourth transfusion than at the start, whereas four transfusions of blood from an obese plethoric, cyanotic woman with six million red cells and one hundred and ten per cent. of hemoglobin increased the patient's cell in six weeks to two million and eight hundred thousand and the hemoglobin to fifty-five per cent., with improved general condition and appetite. The greater benefit from plethoric blood is not due to the larger number of erythrocytes injected, but to the fact that such blood contains active hematopoietic substances. In rabbits the authors noted a far greater cell response after injection of plethoric than after normal blood. The manner in which plethorics react to bleeding shows plainly that their blood possesses tremendous reparative power. The plethoric donor in question, although bled ten times in three months to a total of three and one half to four litres of blood, showed little change in the red cell count.

Effect of Röntgen Ray Irradiation on Red Blood Cell Production in Cancer and Leucemia.—Raphael Isaacs (*American Journal of the Medical Sciences,* January, 1926) presents the following conclusions: Irradiation stimulates in susceptible cases changes which are normal in the life of a red blood corpuscle, the rate and time of initiation only being changed. Effective short wave röntgen ray irradiation over any part of the body in man may be followed, in from one to twenty-four hours, by one of three responses of the young red blood cells. The granule red cells may show an appreciable and sustained increase in percentage, or the increase may be transient, or it may be negligible. Cases of cancer and leucemia in which the increase of granule red corpuscles after irradiation is significant and sustained for two or more days show a definite clinical improvement and no leucopenia develops. When there is no such increase, there is usually no clinical improvement. When the increase is for twenty-four hours or less and followed by an abrupt decrease, the results are those of too much irradiation, a leucopenia develops, and the patient may become worse clinically. The most frequent effect on the count is a gradual temporary decrease, with an increase in the color index. The change in the percentage of immature red corpuscles is one of orderly stimulation to reach maturity, follow therapeutic irradiation over any region of the body, and appear to be a systemic effect. The period between the irradiation and the beginning of maturation changes in the red blood cells is probably a matter of minutes, as compared with hours or days for the leucocytes and weeks for carcinoma tissue. All röntgen ray irradiation may be considered as stimulative. Small doses may stimulate to division, large ones to maturity and to death from senility.

Four Cases of Hemorrhagic Purpura with Splenectomy.—Herbert Z. Giffin (*Medical Clinics of North America,* January, 1925) reports both severe and mild types of hemorrhagic purpura. Splenectomy has been surprisingly effective in causing a disappearance of almost all of the features of the disease. The improvement following operation is just as prompt and much more spectacular than improvement following splenectomy for hemolytic jaundice.

It is necessary to differentiate hemorrhagic purpura from hemophilia, acute aplastic anemia, certain forms of acute leucemia with hemorrhagic manifestations, cases of multiple telangiectases with secondary bleedings, and a certain group of cases which might be termed familial epistaxis. Rarely a case is seen in which characteristics do not conform definitely either to hemophilia or to hemorrhagic purpura. In the differentiation of acute aplastic anemia with hemorrhagic manifestations and hemorrhagic purpura, the persistent leucopenia may be of very great importance. The reduced number of platelets, the long bleeding time, the absence of retractility of the clot, and the presence of petechiæ on the application of a tourniquet, are the features which will usually clearly differentiate hemorrhagic purpura from any of the other diseases mentioned. The absence of a family history of hemophilia and the absence of hemophilic joints are also of especial importance in the diagnosis.

The spleen was palpable at the time of operation in only two of these four patients. One of the spleens seemed to be considerably enlarged. It seems that in this disease the organ is filled with an abnormally large amount of blood.

The author's observations in general suggest that the average level of the platelet count is low before operation, with an occasional rise to normal, and that, on the other hand, the platelet level after operation is high, with an occasional drop below 100,000. There seems to be considerable evidence which indicates that platelet destruction may be a fundamental factor in the disease. The very rapid increase in the number of platelets following splenectomy, accompanied by the immediate cessation of hemorrhages, could best be explained by the immediate cessation of the excessive destruction of platelets.

Blood Transfusion: Its Dangers and Limited Value.—J. F. Baldwin, (*American Journal of the Medical Sciences,* July, 1925) reaches the following conclusions:

Transfusion is a procedure by no means free of dangers, some of which are absolutely unavoidable.

It is of no value in acute sepsis, but its use in that condition is particularly dangerous.

In chronic sepsis its value is only in improving the anemia when that has reached a more or less dangerous point.

It is of no use in burns except in chronic stages when the main condition is that of anemia.

It is of no ultimate value in pernicious anemia, but its use is attended with more or less hazard, so that it is questionable if the end results are of any real benefit.

Its chief value is in conditions of profound shock or acute anemia from hemorrhage, as in postpartum hemorrhage, ruptured ectopic pregnancy and so forth. Particularly is it of value when given immediately preceding or following some operative procedure in which acute hemorrhage forms an important factor.

It seems to have little or no value in shock unless that shock is the result of acute hemorrhage.

Its very great value in hemorrhages seen occasionally in newborn infants has apparently been conclusively established. It seems to be in such conditions unnecessary to type the mother's blood, which can be taken at once and the injection of a small amount into the vein of the infant, or preferably perhaps into the superior longitudinal sinus, may prove a lifesaving procedure.

Hemochromogen Crystal Test for Blood.—Douglas J. A. Kerr and Victor H. Mason (*British Medical Journal,* January 23, 1926) prefer Sutherland's method with the Takayama solution No. 2 for the production of the hemochromogen crystals in the blood. This solution consists of sodium hydroxide (ten per cent.) three c.c., pyridine three c.c., saturated solution of grape sugar three c.c., and distilled water seven c.c. The solution deteriorates after one or two months. On the addition of two or three drops of Takayama's solution to a small piece of the suspected material on a slide, in the cold, and covering with a coverglass, salmon pink crystals appear within one to six minutes, giving a very characteristic appearance under the low power of the microscope. At the same time, the color changes through greenish brown, dark red, to pink, indicating the formation of hemochromogen, and thus affording confirmation of the test. If only a minute portion of blood is available this is apt to vanish during any process of heating, and thus a method which can be carried out in the cold possesses a distinct advantage.

In the majority of cases, especially with fresh stains and if care be exercised, there is no difficulty in obtaining hemin crystals. This test has the following advantages:

1. Simplicity of technic, being obtained in the cold by simply adding the Takayama No. 2 solution.
2. If it is desired to heat the slide, there is no danger of overheating as there is in the case of hemin crystals.
3. The crystals are large, easily seen, and are of a very characteristic appearance and color.
4. The nature of the crystals may be confirmed by means of the spectroscope.

The Sugar Content of Blood.—Ben K. Harned (*Journal of Biological Chemistry,* October, 1925) reports a method of determining the sugar in the blood which closely agrees with that of Benedict's recent method. In Harned's procedure, the blood proteins are precipitated by a slight excess of acid mercuric nitrate. Excess of mercury and unoxidized nitrogen are removed from the filtrate by successive precipitation by sodium bicarbonate and hydrogen sulfide. The final filtrate is substituted for the tungstic acid filtrate in the Folin-Wu procedure. Glucose added to the blood is quantitatively recovered. The Folin-Wu values for blood sugar average from seventeen to twenty-five per cent. higher than those by the proposed procedure.

Medicolegal Notes.

RIGHT TO PHYSICAL EXAMINATION OF PLAINTIFF IN PERSONAL INJURY ACTION

The Connecticut Supreme Court of Errors holds, Cook v. Miller, 130 Atl. 571, that in an action for personal injuries an order of the trial court for an examination of the plaintiff's person is a proper exercise of its discretion. The court said: "The discretionary right to make such an order would seem to flow legitimately from the right of a defendant to call an injured plaintiff as a witness and compel his testimony as to his injuries, or to cross examine him relative thereto, if he testifies in his own behalf. While in a number of states this matter is one of statutory regulation in the states where no such regulation obtains the decided preponderance of authority favors the right of the trier in his discretion to make such an order."

AWARD SUSTAINED AGAINST MEDICAL EVIDENCE AS TO CAUSE OF GANGRENE

The New Jersey Supreme Court held, Curtis-Warner Construction Corp. v. Gorman, 130 Atl. 538, that evidence that a block of timber struck claimant on the foot; that, while the injury appeared trivial at first, it developed so that he had to go to the hospital; that he had pneumonia; that gangrene set in at the point of injury; and that he lost a portion of his foot, sustained an award of compensation, although there was medical testimony to the effect that the gangrene was not the result of the accident, but of the pneumonia.

ACCELERATION OF TUBERCULOSIS BY INJURY

In a workman's compensation case, where the claimant was suffering from tuberculosis following an injury caused by being squeezed by a heavy oaken door against the wall while the door was being moved, the employer contended that no causal connection had been shown between the alleged injury and the tuberculosis. The defendant produced two very distinguished medical specialists in tuberculosis. They testified hypothetically only. This testimony was that tuberculosis results from infection and never from traumatism. They did not deny, but impliedly admitted, that tuberculosis might be accelerated and lighted up by traumatic causes; but they also testified that the injury to this patient, as described in the hypothetical question, was not adequate to produce such acceleration. The Iowa Supreme Court, Fraze v. McClelland, 205 N. W., 737, held that the testimony of the specialists was entitled to great weight, and it was disposed, in the consideration of this case to assume as a fact that tuberculosis does not originate from traumatic causes. It was conceded by a medical witness for the plaintiff that the tuberculous infection of this patient must have occurred in his childhood. He gave as his opinion also that the injury to the plaintiff might have so devitalized the injured region in the chest as to stimulate or lighten up the tuberculous condition.

It was undisputed that immediately following the injury the plaintiff's weight decreased from about 165 or 170 pounds to 135 pounds, and that the development of his disability from that date was much more rapid than the normal progress of tuberculosis under ordinary conditions. In his opinion filed, the Industrial Commissioner cited decisions from the courts of last resort of three states, wherein it was found that acceleration of pulmonary tuberculosis had resulted from traumatic causes. Retmier v. Ceruse, 67 Ind. App. 192; State v. District Court, 138 Minn. 334; Lundy v. George Brown & Co., 93 N. J. Law 107.

The Iowa court was not disposed to establish or to contradict medical facts by judicial precedents, being of opinion that whatever the medical facts be, as proven in a particular case, they must control regardless of judicial precedent. But the records in the cited cases indicated that it was far from settled medically that traumatic causes may not greatly stimulate and accelerate the action of a dormant tuberculous affection; and such was the disclosure of the record in the present case. The court regarded the evidence as close on the question of causal effect, but thought also that the plaintiff's evidence was sufficiently preponderant to sustain the action of the Industrial Commissioner in allowing compensation.

MEMORANDUM OF SALE OF ARSENIC HELD INADMISSIBLE IN MURDER CASE

In a prosecution for murder by poisoning with arsenic the Illinois Supreme Court held, People v. Zalimas, 319 Ill. 186, 149 N. E. 759, that a druggist's memorandum of a sale of arsenic bearing the accused's name as the purchaser was not admissible as original evidence, but it was proper for the maker as a witness to use it to refresh his memory and, after doing so, to testify to such facts as he was then able to remember. He did so testify, but his memory did not enable him to recall the purchaser as the accused. He did not know the name of the purchaser, but inserted in the memorandum the name the unknown purchaser chose to give him. It was held error to admit the memorandum in evidence, and there was no evidence connecting the accused with the purchase of arsenic. It was also held that the fact that a wholesale drug store sold a retail drug store a pound of arsenic in August did not tend to prove that the retail drug store sold arsenic to the accused three months later in November. The only effect of this evidence was held to be to attach a fictitious importance to the sale by the wholesale company to the retailer, and its admission was held prejudicial error.

TAX FOR ERECTION AND UPKEEP OF HOSPITAL HELD AUTHORIZED

The Kansas Supreme Court holds, Atchison T. & S. F. Ry. Co. v. McPherson County Comrs., 241 Pac. 444, that section 1 of chapter 202 of the Laws of 1913 authorizes the board of county commissioners, after the hospital proposition provided for therein has been adopted by the voters of the county, to levy annually thereafter a tax of two mills on the dollar for the purchase of a site, for the erection of buildings and for the support of the hospital.

PUNCTURE BY TUBE IN TREATING HEMORRHOIDS HELD ACCIDENT

The Indiana Supreme Court holds, Hoosier Casualty Co. v. Royster, 149 N. E. 164, that death caused by an insured unintentionally puncturing his bowels by inserting a tube used for introducing medicine in treating hemorrhoids beyond the point intended occurred through external, violent and accidental means within the meaning of the policy sued upon.

FALSE REPRESENTATIONS AS TO HOSPITAL TREATMENT VOIDING INSURANCE POLICY

The New York Appellate Division holds, Grubiak v. John Hancock Mut. Life Ins. Co., 208 N. Y. Supp., 279, that since the adoption of section 58 of the New York Insurance Law, false representations by an insured in his application that he had never been treated in a hospital precluded recovery on the policy, although the agent who acted for the insurance company in soliciting the insurance and the doctor who examined the insured for the company were both aware of the true facts, and knew they were not stated in the application.

Experimental Evidence of the Relation of Dental Infection to Systemic Disease*

RUSSELL L. HADEN, M.D.
Kansas City, Missouri

Few clinicians today doubt a close relation between systemic disturbances due to focal infection and chronic periapical dental disease. Results obtained clinically in some patients by the removal of the localized infections suggest an etiological relationship. In many instances, however, such definite evidence is lacking. This does not prove that the focal infection is not the cause of the systemic disease. Often the anatomical changes are such as to preclude a cure. Here, only a prevention of the recurrence of the symptoms or a stay in the progress of the disease is the most that one can hope for. Most of the laboratory procedures which have been employed in attempts to prove a causal relation of the focal lesion to distant disease have been found of little value. Complement fixation reactions, blood chemical changes, and morphological blood studies have all failed to give dependable findings.

Certainly the most convincing proof we have of the relation of a given focus to disease is the reproduction in animals with the organism recovered from the focus of the condition from which the patient suffers. Such proof depends upon the tendency of bacteria to localize in certain tissues of the body due to some peculiar inherent property. Rosenow, in many experiments, has shown that bacteria from chronic foci, if etiologically related, tend to reproduce in animals the lesions from which the patient suffers. Many other workers have not been so successful in demonstrating specific localization. I have been able to present confirmatory results in disease of the eye (1), the stomach (2), and the kidney (3), and in cases of onychia (4). Failures in the hands of other workers are evidently largely due to the fact that mediums providing gradient oxygen tension were not used in making the cultures and that the organisms were not transferred rapidly enough from the patient to the experimental animal.

The following case histories with the result of animal experiments are reported to illustrate the method of proof by animal experimentation. Details of the methods employed in obtaining the culture material and making the culture have been described in detail elsewhere (1). All cultures have been made in deep tubes of glucose brain media which provide all degrees of oxygen tension and preserve the specific affinity of the organisms. The animals have been inoculated intravenously with five c. c. of the original broth cultures of the infected material. The culture employed is never over and often less than twenty-four hours old. The animals have been autopsied routinely three to six days after the injection.

*From the Deaner Institute, Kansas City, Mo.

GASTRIC ULCER

CASE I.—History: E. W. C., aged thirty-two, complained of a severe gnawing pain in the abdomen, occurring from three to four hours after eating. The past history was unimportant. The physical examination was negative except for tenderness in the appendix region. The gastric analysis showed forty acidity per cent. of free hydrochloric acid, and fifty-seven acidity per cent. of total acid. The hemoglobin was eighty-five per cent., the red count 4,910,000, and the white count 12,200. The urine showed only a trace of albumin. The x ray findings were typical of ulcer. The clinical diagnosis was gastric ulcer. The dental radiographs showed three pulpless teeth, two of which showed no apical rarefaction.

Animal inoculations: From the extracted teeth a profuse growth of streptococci was obtained. A fourth tooth was removed for extensive pyorrhea. Eight rabbits were injected intravenously with the broth cultures. Four of the eight showed gross lesions in the stomach or duodenum (Fig. 2). Six of the animals showed also involvement of the joints; three had muscle lesions, two had kidney lesions, and one, a lesion in the heart muscle.

ACUTE MYOCARDITIS

CASE II.—History: D. M., a medical student, aged twenty-four, stated that he had had several acute attacks of rapid heart beginning at the age of twelve. There was no history of coincident infection at the onset. At the age of eighteen an attack occurred with an abscessed tooth. In May, 1925, he had an attack lasting several hours during which electrocardiograms were taken. These showed the tachycardia to be of a ventricular type (Fig. 3A). For several weeks before this attack he had had an infection around a partially erupted third molar tooth. A second electrocardiogram taken in June, 1925, showed

Copyright, 1926, by A. R. Elliott Publishing Company.

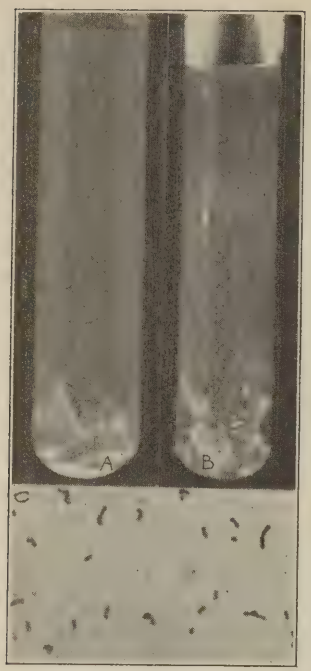

Fig. 1.—A, Culture from periapical dental infection in deep tube of glucose brain agar. Note the uniform growth throughout tube; B, culture similarly made from another tooth. This organism will not grow in the aerobic zone, as shown by the absence of colonies at the top of the agar column; C, typical short chain streptococcus from a periapical infection.

a normal heart rate but evidence of myocardial disease (Fig. 3B).

Animal inoculations: At this time the third molar tooth was removed, revealing a pocket of pus from which a pure culture of a streptococcus was obtained. Two rabbits were injected with this culture. One died forty-eight hours later. At autopsy there were numerous areas of hemorrhage in the heart muscle (Fig. 3D). The other animal was killed. This also had a smaller number of hemorrhages in the heart muscle.

Subsequent course: In October, 1925, the patient had another attack, during which he died. At autopsy the heart showed no gross lesions. Sections, however, showed areas of acute infection in the heart muscle (Fig. 3C).

RECURRENT IRITIS

Case II. — History: E. O. M., a clerk, aged fifty-two, had had the first attack of iritis in 1905 and the second in 1909. Following this he had had frequent attacks at intervals of about one year. During the past two years he had suffered from iritis almost continuously in a subacute form. The patient stated that the most severe attack he had ever had occurred while some dental work was being done. He had been confined to bed for four months in 1920 with rheumatism.

Fig. 5.—A, original culture tube from the lateral incisor indicated by arrow in B of patient suffering from duodenal ulcer (Case IV); B, dental radiograph of tooth from which the culture at left was grown; C, massive hemorrhage in duodenum of rabbit injected with a culture from the lower incisors.

An examination of the right eye, May 20, 1922, during a period of active infection, showed posterior synechiæ, plastic exudates in anterior chamber, and a small hemorrhage at the periphery of the iris. There was much pericorneal injection, deep and superficial. The intraocular pressure was normal. There was intense photophobia and lacrimation. The left eye showed no active infection but posterior synechiæ were present, indicating that there had been attacks of iritis in this eye also.

A physical examination, November 21, 1922, revealed a well compensated aortic insufficiency. The Wassermann test and urine examination were negative. A blood count showed 4,124,000 red cells, 8,350 white cells, and the following differential; polymorphonuclear neutrophiles, 68.2 per cent.; polymorphonuclear eosinophiles, 7.2 per cent; small mononuclears, 17.2 per cent.; large mononuclears 7.4 per cent. The dental radiograms revealed nine pulpless teeth only one of which, the lower left first bicuspid, showed a definite area of rarefaction.

Fig. 2.—Ulcer of stomach of rabbit following the injection of culture from teeth of patient (Case I) suffering from gastric ulcer.

Animal inoculations: The root tip of the lower left first bicuspid showed an infinity of colonies of a green producing streptococcus in the brain agar culture. The mixed broth cultures from this tooth and the upper left first bicuspid, however, produced no eye lesions in rabbits. The four upper incisors (Fig. 4B) were removed at one operation. The upper right lateral was sterile, even in broth, the left central and lateral showed Streptococcus salivarius, and the right central, Streptococcus fecalis.

Two rabbits inoculated with the mixed cultures manifested a marked iritis (Fig. 4A and C). At necropsy one showed cloudy fluid in the joints with an abscess of the kidney; the other no lesions except that of the eyes. The upper and lower right second molars showed a profuse growth of staphylococci and streptococci. Two rabbits inoculated with the mixed cultures showed marked bilateral circumcorneal injection with a purulent arthritis and abscess in the kidney, voluntary muscle and heart.

DUODENAL ULCER

Case IV.—History: J. J. W., a plumber, aged thirty-two, gave a typical history of recurring attacks of duodenal ulcer over a period of six years. The present attack had begun five weeks before he was first seen and had been unusually severe. He was in a good state of nutrition. The tonsils were small and no pus could be expressed. The heart sounds were clear, the pulse 80/100 and the blood pressure 140/100. There was tenderness in the epigastrium. The radiograms of the teeth showed a large area of bone resorption around the lower right and left lateral incisors (Fig. 5B). On culture there was a profuse growth of streptococci which would not grow to the top of the culture tube (Fig. 5A). There was also an area of questionable infection at the site of extraction of another tooth. Following the extraction of the teeth the symptoms were relieved.

Animal inoculations: Two rabbits were injected with the mixed cultures from the two incisor teeth. Both were killed the following day. One showed a

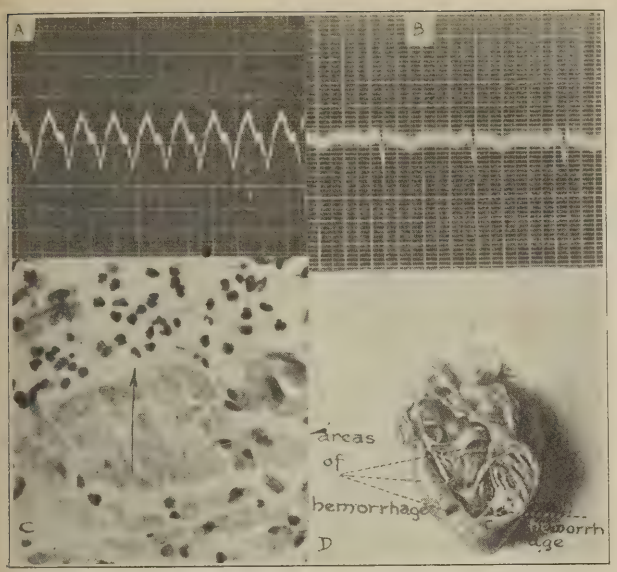

FIG. 3.—A, Electrocardiogram of patient (Case II) taken during an attack of paroxysmal tachycardia; B, electrocardiogram of same patient taken one month after attack. Note the evidence of myocardial disturbance as shown by the inverted T-wave and abnormal Q R S interval in lead I; C, photomicrograph of patient's heart muscle obtained at autopsy; note the areas of polymorphonuclear infiltration; D, heart of rabbit injected with streptococcus from an infected abscess around a partially erupted third molar tooth of the patient.

massive hemorrhage in the duodenal bulb (Fig. 5C) with no lesions elsewhere. The other showed one

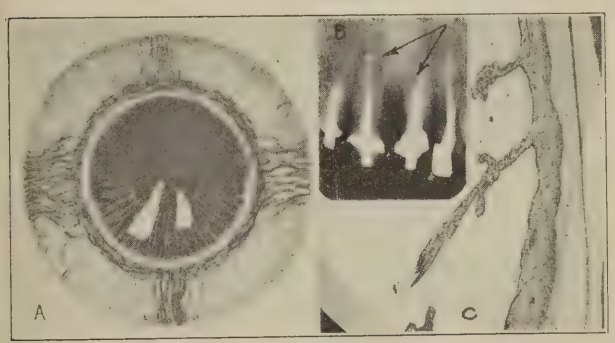

FIG. 4.—B, Upper incisors of patient (Case III) suffering from recurring attacks of iritis; A, eye of rabbit injected with the cultures from the incisor teeth shown in radiograph at left; C, photomicrograph of eye shown in A. Note the injection of iris and ciliary body.

moderate sized hemorrhage in the first third of the duodenum and a slight purulent arthritis.

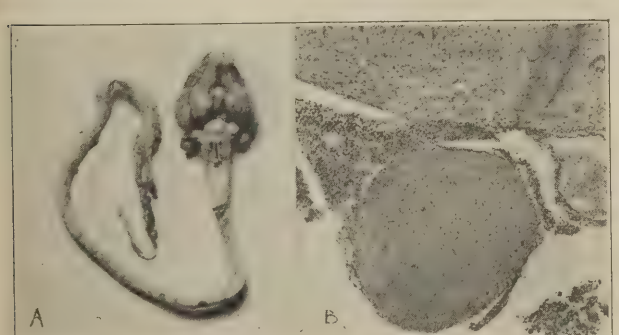

FIG. 8.—A, brain and spinal cord of rabbit injected with cultures from the teeth of a patient suffering from acute facial paralysis. There is marked injection of the base of the brain and injection and hemorrhage in the condal end of cord; B, photomicrograph of one of the cranial nerves at the base of the brain shown in A. Note the exudate at the base of brain partly encircling the nerve.

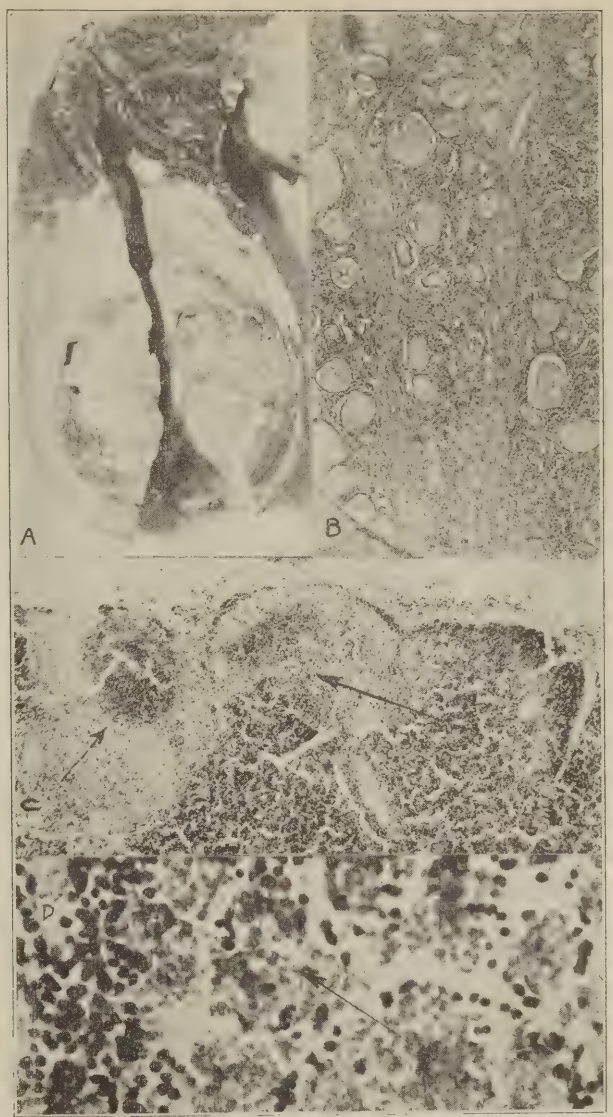

FIG. 7.—A, thyroid gland of patient suffering from ligneous thyroiditis; B, photomicrograph of section from gland; note the marked fibrosis; C, lymph gland adjacent to thyroid of rabbit injected with cultures from teeth of patient; note the necrosis and inflammatory reaction; D, photomicrograph at higher magnification of same section.

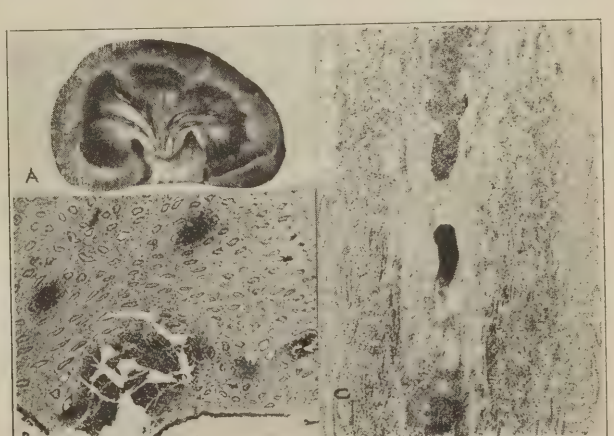

FIG. 6.—Kidney of rabbit injected with cultures from teeth of patient (Case V) suffering from pyelonephritis. A, gross specimen showing abscesses in the medulla; B, low power photomicrograph showing abscesses one of which is breaking through into the pelvis; C, photomicrograph through a lesion in the kidney medulla showing the necrosis and polymorphonuclear infiltration.

CHRONIC PYELONEPHRITIS

Case V.—History: M. I., a housewife, aged forty-five, had had frequent attacks of tonsillitis and quinsy before a tonsillectomy was done in May, 1922. She had had pyuria for twenty years and had been given pelvic lavage in 1915 without improvement. When first seen in January, 1923, she had been confined to bed for several months with myocarditis. Recently she had had an attack of acute arthritis involving several of the larger joints.

The physical examination was negative except for evident myocarditis. The blood count showed 4,000,000 red cells, 10,500 white cells and the following differential: polymorphonuclear neutrophiles, 59.6 per cent.; eosinophiles, 3.2 per cent.; basophiles, 0.6 per cent.; lymphocytes, 32.2 per cent., and large mononuclears, 4.4 per cent. The urine contained a very large amount of pus, a moderate amount of albumin, but no red cells or casts. The radiograms showed four pulpless teeth, only one of which had an area of apical rarefaction.

Animal inoculations: The pulpless teeth were extracted. Green producing streptococci were recovered from all of them. Four rabbits were injected with cultures. All showed at autopsy multiple abscesses (Fig. 6) in kidney medulla. All had purulent fluid in joints and five showed muscle lesions.

This patient was seen again nine months later. The heart and joint symptoms had disappeared. The urine contained only a small amount of pus.

SUBACUTE THYROIDITIS

Case VI.—History: M. A. M., a housewife, aged thirty-eight, complained of a cough, dyspnea, a painful swelling of the neck, nervousness and loss of weight. She had always been well before the present trouble. Her present illness had begun four months before admission with a swelling of the neck followed by symptoms of pressure on the trachea. She had difficulty in breathing and had lost thirty pounds.

On examination the patient was nervous, had inspiratory dyspnea, marked dental infection and diseased tonsils. There was swelling with marked induration of the tissue of the neck on both sides in the region of the thyroid. The swelling was tender and of woody hardness. There was a slight tremor of the hands. There was no anemia, the white blood count was 14,200, the Wassermann test was negative. The basal metabolic rate was twenty-six per cent. She had a slight daily rise in temperature. The radiograms showed the trachea deflected to the left and compressed. There were eleven pulpless teeth and marked pyorrhea.

Her condition grew steadily worse until operation was required to relieve the tracheal stenosis. A mass of tissue including the right lobe of the thyroid about the size of a hen's egg was removed. It was hard and cut with increased resistance (Fig. 6A). The cut surface showed hyaline fibrous tissue, round cell infiltration and areas of chronic inflammatory reaction in which there were nests of thyroid follicles (Fig. 6B). A diagnosis of chronic thyroiditis with extensive fibrous encapsulation was made.

The removal of the thyroid gave immediate relief but the symptoms returned several weeks later and necessitated a tracheotomy.

Animal inoculations: On June 30th, three pulpless teeth were extracted. A green producing streptococcus and a staphylococcus were recovered from all. Two rabbits were injected. At autopsy lesions in the muscle joints and kidney were found but no lesions in the thyroid or thymus. Three days later four other teeth were extracted. All showed a profuse growth of staphylococci and streptococci. One of the rabbits injected died within a few hours. There were numerous hemorrhages in the thymus and thyroid. The lymph glands adjacent to the thyroid were swollen and hemorrhagic. The following day the second rabbit injected was killed. There were marked pericorneal injection and numerous hemorrhages in the thymus. The lymph glands around the thyroid showed extreme edema, many hemorrhages and beginning necrosis. Another rabbit was injected with the same culture and killed the following day. The lump gland around the thyroid showed only a few hemorrhages. There were no other lesions.

Following the extraction of the first group of teeth which produced no special lesions in animals there was no reaction on the part of the patient. The reaction following the extraction of the teeth, the cultures of which produced specific lesions suggestive of those from which the patient was suffering, was severe. The temperature went up, the patient became excited and continued so for several days.

Following this reaction there was a gradual improvement in the symptoms. Two months later she had gained fifteen pounds in weight. The temperature and pulse were normal. The swelling of the neck completely disappeared and the induration of the tissues had almost disappeared. A year later there had been no return of active symptoms, but a permanent paralysis of the laryngeal nerve existed.

ACUTE FACIAL PARALYSIS

Case VII.—History: L. M. H., a plumber, aged thirty-nine, complained of facial paralysis. One year previously he had suffered from dizzy spells, and on examination was found to have albumin in the urine. The facial paralysis had appeared suddenly five days before without any pain. The right side of the face was found to be completely paralyzed. No other cranial nerves were involved. The blood pressure was: systolic, 130; diastolic, 85. There was no anemia. The dental röntgenograms showed four pulpless teeth, all presenting evidence of periapical infection.

Animal inoculations: Three rabbits were injected with the mixed cultures from the four extracted teeth In one a paralysis of the hind legs developed forty-eight hours after injection and was killed. At necropsy all organs were negative except the brain and spinal cord, which showed marked injection, some exudate at the base of the brain (Fig. 8) and hemorrhage in the caudal end of the cord. The second rabbit showed no symptoms at any time, and, at necropsy, only some vegetations on the heart valves were found. The third rabbit, two days after injection, had paralysis of the left ear and a pericorneal injection, which gradually cleared up. When the animal was killed, the only lesions found were a purulent arthritis.

The Placing of Thoracoplastic Cases in General Surgical Wards and Their Medical Care Thereafter*

S. ADOLPHUS KNOPF, M.D.
New York

(*Concluded from page* 718)

Since, according to the foregoing report,[1] we have the right and privilege to place patients suitable for thoracoplasty in the surgical wards of general hospitals, may we now see what can be done from a medical point of view to give these patients the best possible care in cooperation with our surgical colleagues. To this end let us start with the presumption that the most careful attention has been given to the patient prior to his thoracoplastic operation and that his resistance has been increased as much as possible, so that both physically and mentally he is prepared for the surgical shock. This shock is, of course, greatly minimized by the use of local instead of general anesthesia, and by the graded operation.

There is nearly always danger that a patient may vomit during the anesthesia and that the aspiration of food particles may result in an aspiration pneumonia. As a preoperative precaution, therefore, the surgeon as well as the anesthetist should make sure that the patient's stomach is virtually empty, and in doubtful cases it may even be advisable to resort to lavage of the stomach prior to the beginning of anesthesia. The anesthetist should see that the foot end of the operating table can easily be elevated so that when he notices any diaphragmatic contraction during anesthesia, indicating the possibility of the patient's vomiting, he should immediately raise the lower portion of the body and thus facilitate the expulsion of the stomach contents.

I am opposed to ether anesthesia for all kinds of tuberculous patients, and particularly in operations involving the abdominal or thoracic cavities or the upper respiratory or digestive tract. All operations in these regions should be preceded by a thorough cleansing of the nasal and buccal cavities. One can never be sure of the type of pneumococci the patient may be harboring in his mouth, nose, and throat. During the recent war it was my privilege to publish, by authority of the Surgeon General, an article entitled Pneumonia Among Soldiers in Camps, Cantonments, and at the Front. As a means of disinfecting the upper respiratory and digestive tracts and perhaps killing the virulent types of pneumococci, I suggested the following solution which had been recommended by Kolmer and Steinfield (2):

	gm. or c.c.
Ethylhydrocuprein hydrochloride or quinin bisulphate	0.005
Liquor thymolis	5.0
Distilled water, sufficient to make	50.0

Before the final cleansing of these regions with the solution indicated, an important measure against the aspiration of infected material from bronchial secretions or cavities consists in urging the patient to repeat his usual morning pulmonary toilet once more an hour before the operation. Nearly all tuberculous patients cough more freely in the morning and expel profusely the secretions accumulated over night.

Let us for a moment consider the symptoms which may arise after the operation and which should be treated or rather anticipated by the surgeon in attendance, if this has not already been done by the medical attendant prior to the patient's transference to the surgical service. It is presumed, of course, that the patient's resistance has been built up and his general physical and mental condition prepared for the surgical procedure. I question the wisdom of telling the patient that because he will be given local anesthesia he will feel no pain at all during the operation. I would rather tell him it may hurt some, but assure him that with a little courage he will be able to stand the pain. It is always surprising to see how much a soothing word from a gentle voiced physician or nurse helps the patient to bear the pain which is often inevitable with local anesthesia.

The patient's condition should be an index to the number of ribs to be dissected at one seance. Although the patient may be asked how he feels and whether he could stand the removal of another rib, his own feeling, influenced by the administration of the opiate preceding the operation and the local anesthesia, may lead him to think that he can well stand the prolongation. However, his pulse, the character of his respiration, and his general aspect should be the decisive factors. I believe no harm has ever been done by making the graded operation even more graded than originally intended.

The most distressing symptom from which the majority of tuberculous patients suffer is cough, and it becomes especially troublesome and painful when the secretions are tenacious. I know of no better way to overcome this than to administer to the patient as large a quantity of chloride of sodium as he can take with his food, and begin with this several days before his operation. His desire to drink water is naturally increased and unless the patient has diarrhea, only good can come from this. While I do not pretend to be able to explain exactly why this increased amount of salt should help so materially in lessening the tenacious quality of the sputum, we may perhaps presume that it is effected by the process of osmosis. Be this as it may, I know from experience that it is as good a dietetic remedy as we have to ease the cough and to facilitate the ejection of the sputum.

Very varied indeed is the experience with cough after the completion of thoracoplastic operations. I have asked quite a number of surgeons to be good enough to answer the following question: "Does the average tuberculous patient, after having been submitted to a graded thoracoplastic operation, cough

*Read by invitation before the Eighth Annual Meeting of the American Association for Thoracic Surgery, Washington, D. C., May 5, 1925.

[1]Published in the MEDICAL JOURNAL AND RECORD for May 19, 1926.

more or does he cough less, and is the quantity of sputum increased or diminished?"

In the experience of Archibald, Graham, Green, Keller, Lambert, Lilienthal, and Whittemore there is a diminution of cough and sputum immediately after the thoracoplastic operation. On the other hand, Meyer, Ramsdell, Torek, and Wells have found that

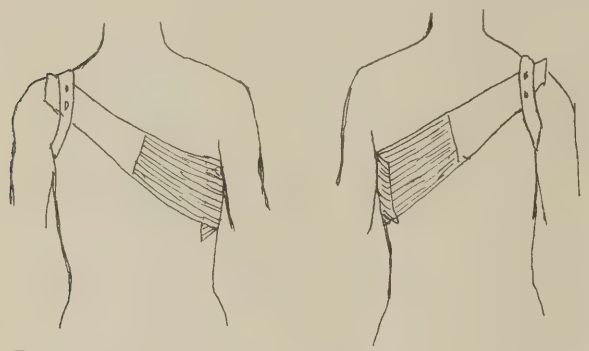

Fig. 1.—Edison's adhesive strap for compression of upper portion of lung; front and back views.

cough and sputum are increased in the first few days or a week after the operation and later gradually diminished.

After an operation on the chest, cough is just as painful and distressing as it is after an abdominal or pelvic operation, perhaps even more so, and whatever can be done to diminish its frequency without suppressing the secretion will be of advantage and hasten the patient's recovery. However, it must be borne in mind that for several days immediately following the operation, it is of the greatest importance in the prevention of aspiration or statis pneumonia to urge the patient not to suppress the cough with expectoration, in fact to let him do this as often as he can, to get rid of infectious secretions. By supporting the operated side with his hand or having the nurse do this, when the patient expects to cough, the pain and effort will be materially lessened.

It is, of course, presumed that most patients coming to thoracoplasty have learned to discipline their cough and to cough only if they feel they must expectorate. Nevertheless, it may be well to impress upon the patient again that the useless cough, that is, the cough without expectoration, can be avoided by will power. This will power, however, may not be as strong as it was before the operation and it sometimes becomes necessary, for a short period of time, to administer some cough remedy. I know of no better medicinal agent than small doses of heroine. I am in the habit of giving one twelfth of a grain of heroine every four or six hours and decreasing the frequency as the cough subsides. I have found the following a very pleasant mixture to administer this narcotic:

		gm. or c.c.	
Heroinae hydrochlor	gr. ij;		130
Acid. sulphuric. dil. .....m	xlv;	3	
Glycerinae	ʒj;	32	
Aq. laurocerasi, }		{ 16	
Syrup. pruni virg. } āā.....	ʒiv;	{ 16	
Aquæ distillatæ .....q. s. ad.	ʒiij.	90	

M. Sig.: One teaspoonful every 4 to 6 hours; take less as cough subsides.

To avoid any possible addiction to the use of heroine, as soon as the cough begins to lessen I alternate the heroine mixture with one wherein the active principle is codeine in doses of one eighth of a grain. For great mental distress or apprehension and for physical pain likely to follow the operation, I believe it is customary for surgeons to administer a fairly good sized dose of morphine hypodermically. It may be necessary to repeat this a few times after the operation.

The complication which is most feared after a thoracoplastic operation is of course the aspiration pneumonia in the healthy or relatively little invaded apex. We have already indicated the measures to be taken to avoid aspiration of food particles during anesthesia. To avoid the aspiration of infectious material coming from diseased bronchi or pulmonary cavities I know of no better means than to restrict the respiratory movements in that region. This may be done by strong adhesive straps after the method devised by Edison (Fig. 1). The old fashioned adhesive plaster may be advantageously replaced by the elasticon, suggested by Dr. Lilienthal and manufactured by Johnson & Johnson of New Brunswick, N. J. This is not irritating and will be borne better by the patient than even the best old fashioned adhesive straps.

Partial immobilization may also be obtained by a plaster of Paris short jacket, as devised by Forster of Colorado Springs (Fig. 2). This latter permits the compression of the apex or the upper lobe in part or entirely with the aid of inflatable rubber bulbs; Sewall's belt (Fig. 3) may also serve, or my own saddle bag (Fig. 4), which can be made in any size. It consists of a weighted band placed across the opposite side of the chest when the patient is in the recumbent position. By putting sand or shot in the container, the weight of the bag can be regulated and it should be placed so as to straddle the nonoperated side and thus inhibit respiration. To retain it in place bands can be attached and tied. The patient should also, of course, be cautioned to avoid deep respiration as far as possible.

Dr. David A. Stewart of the Manitoba Sanatorium

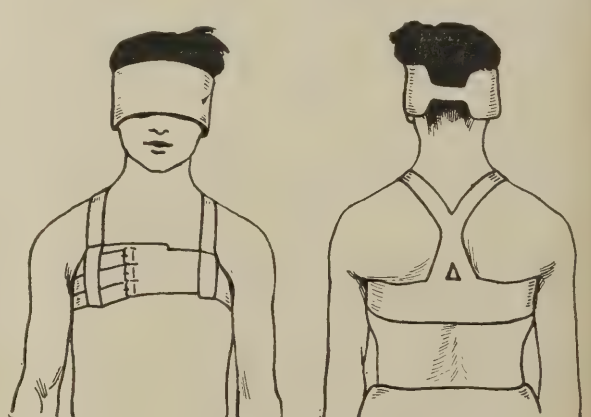

Fig. 3.—Sewall's belt; anterior and posterior views.

has also devised an interesting mechanism whereby he secures partial immobilization and in some cases also a small measure of collapse (Fig. 5). In the prevention of aspiration pneumonia it is of great advantage if for some time before the operation the patient has been taught to use only diaphragmatic respiration, which will be commented on later.

On rare occasions there may be a postoperative rise of temperature, a condition which should of course not be treated by heart depressing remedies, but by aerotherapy and hydrotherapy. It may not be possible to carry out the former as thoroughly with a patient in a general hospital ward as in a private room or sanatorium, but it is presumed that our mod-

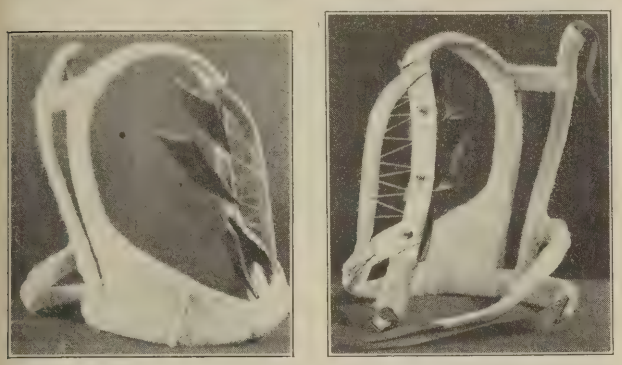

FIG. 2.—Forster's plaster of Paris jacket for restricting respiratory movements.

ern surgical wards are well ventilated and if the patient's bed is surrounded by a cubicle or screen, the window in his cubicle may be opened wider to supply his need for air. I do not believe, however, that the patient who has been operated on should be made uncomfortable in midwinter on account of outside low temperature; extremes should be avoided. He should never be exposed to the danger of being chilled. His body should be kept warm while he breathes fresh air.

If there is an appreciable rise of temperature, it may be well to resort to hydrotherapy by sponging the arms and legs with water at a temperature of from 85 to 90° F., or lower if the patient does not object, every two to four hours. The upper and lower extremities and perhaps also the abdomen should be wrapped in a Turkish towel and the water be allowed to absorb. The thorax should not be disturbed. In this way aerotherapy and hydrotherapy may be judiciously administered while the patient is still in the surgical division of the hospital.

We next come to the period when the patient is discharged as surgically healed, his right or left lung completely collapsed. Thanks to the compression of the diseased lung tissue, he has become virtually afebrile with his cough and secretions considerably diminished. However, the fact remains that probably no patient has ever come to thoracoplasty who has had an absolutely unilateral lesion, for the patients ready to have their lungs compressed are, as a rule, in the third stage of the disease, that is to say, there is extensive localized infiltration or consolidation in one or more lobes or disseminated areas of cavity formation, and when a case has advanced to this stage there is usually an apecial invasion of the other less affected side. In the many years of my service at the New York Health Department's Riverside Hospital for the consumptive poor, where we take only the advanced cases, I do not remember a single absolutely unilateral case. One side may be very little involved, but I repeat that when the patient has reached the stage just described, we can not hope to find an absolutely unilateral condition.

To protect the patient who has one side totally collapsed but has a beginning invasion of the opposite side is the most important thing after thoracoplasty. All our armamentarium—aerotherapy, climatotherapy, mechanotherapy, respiratory therapy, massotherapy, hydrotherapy, heliotherapy, and even psychotherapy—must be utilized to prevent the still existing tuberculous lesion from advancing further, and if at all possible to bring about a complete arrest. To this end the patient should live twenty-four hours out of every twenty-four in air as fresh and pure as is obtainable. The ways in which this can be accomplished will of course vary with the circumstances and the climatic conditions, for no one ideal climate exists; some patients will feel best in cool, some in warmer climates. Those inclined to dry catarrhal conditions will do well in moderately moist climates, those with moist catarrhs in hot dry climates. Where the individual patient can live outdoors the greatest number of hours of the day and the greatest number of days of the year in fresh, pure air with the greatest comfort, there is his ideal climate. Patients in poorer circumstances, as a rule, can not obtain those ideal conditions and they must be content with their home climate. They may, however, seek environments where the air is relatively free from dust and other impurities and obtain as much sunlight as possible.

Of the value of mechanotherapy we have already spoken, and I may say here that even after the patient's recovery from the effect of the operation and aspiration pneumonia is no longer feared, the various appliances described in the preceding pages as useful for the prevention of aspiration pneumonia may be employed continually to restrict as far as possible the respiratory movements in those portions of the lungs invaded by the tubercle bacilli. I often recommend and use these appliances for the restriction of respiratory movements in pulmonary tuberculosis when neither artificial pneumothorax, section of the phrenic nerve, nor thoracoplasty are indicated or possible.

It may seem surprising when I state that in addition to thoracoplasty on one side, the respiratory movements of the remaining portion of the lung can be restricted to the diaphragm and reduced in number. The *modus operandi* for this is the same as that which I devised for controlled diaphragmatic respiration when only the apices or upper portions of the lungs, on one or on both sides, are involved.

FIG. 5.—Stewart's mechanism for securing partial immobilization and a small measure of collapse.

I will give a short description of this method as follows: When being taught the practice of controlled diaphragmatic breathing, it is best for the patient to lie in or on the bed or on a reclining chair, in a semireclining position, with feet extended and slightly separated, which position demands the least cardiac effort against gravity. This position can be obtained in bed by the use of three or four pillows, and on the typical sanatorium reclining chair, by regulating the back so that it will be at an angle of thirty degrees. In this position relaxation is most easily obtained. If the patient is dressed, there must

not be any garments that would restrict the free exercises of the diaphragm and abdominal muscles. The patient must strive to relax in mind and body and is told to imagine that the respiratory movement begins in the toes of his right foot, the inhalation gradually traveling upward as far as the diaphragm on the right side, then crossing over to the left and gradually descending during exhalation onward to the left foot. While, of course, this breathing upward from the toes to the abdomen is merely imaginary, it results in a diaphragmatic breathing, and whatever quantity of air is inhaled passes mainly through the lower portions of the lungs while the upper portions where tuberculous lesions are usually located, are put, if not at complete, at least at comparative rest.

The patient must of course concentrate his mind on this procedure. He cannot and should not be thinking of anything else during this rest breathing period. The surest way to teach the procedure correctly is to ask him, during inhalation and during exhalation as well, to follow in his mind the physician's hand with index finger pointing as it moves in the upward direction from the right toe and over to the left side of the diaphragm, then downward to the left foot. When the physician's finger has arrived at the left side of the diaphragm, it will pause while the patient may hold his breath a second or two, or longer if he can, and then exhale during the downward movement of the finger. The relation of the duration of the two acts should be five for inhalation and four for exhalation. With some patients ten seconds may be spent for the cycle, five for inhalation, four for exhalation, and one for stopping between inhalation and exhalation. With other patients, particularly the more advanced cases, it may be necessary to count rapidly and shorten the cycle. Nearly all patients are able to lessen the number of respirations per minute with absolute comfort by stopping after the exhalation two, three, or more seconds before inhaling again. In fact, one may leave the duration of the interval between each cycle of the respiratory movements to the ability of the patient to remain quiet before inhaling again. If he is able to hold the air from inhalation several seconds longer, he may also do so.

It will often be necessary to repeat this rest breathing procedure several times before the patient has fully grasped the *modus operandi* and does it correctly. A good way for the physician to assure himself that his patient has fully mastered and understood the rest breathing is, while indicating the direction and duration of the inhalation with one hand, to place the other over the upper portions of the lungs, and thus observe whether they are at complete or at almost complete rest, and with his eyes fixed on the abdominal region see that the diaphragm does its work properly. Later on, by placing his own hands, one on his chest and the other on his abdomen, the patient may learn to know whether or not he is doing the diaphragmatic breathing correctly and giving the upper portion of the chest the desired repose.

One thing which is essential is to interest the patient in this rest breathing by explaining to him why this type of breathing is resorted to and the object to be attained. The quieter an organ of the body is kept the less likely it is to become tuberculous and the more easily it is cured. A tuberculous gland heals more rapidly than any other invaded organ in the body. Skin tuberculosis or a tuberculous bone or joint will heal more quickly when put at rest or subjected to as little movement as possible, and so does a lung completely collapsed by artificial pneumothorax or thoracoplasty. Animals which breathe slowly contract pulmonary tuberculosis less readily than those which breathe fast. We have an example in our domestic animals; the cow which breathes sixteen to eighteen times a minute is far more susceptible to tuberculosis than the horse which breathes only eight times. Rest of the invaded lung is the great object which we physicians try to obtain by all possible means that will not harm the patient.

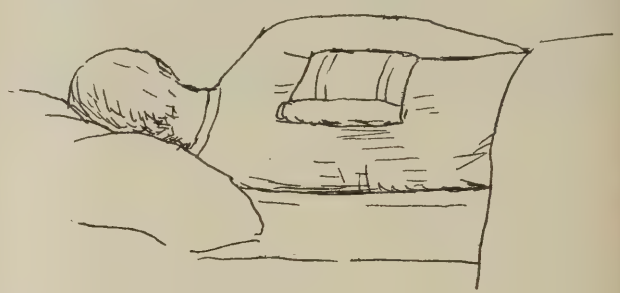

Fig. 4.—Knopf's saddlebag.

It will be surprising if I state how easy it is to train a patient to breathe only with the diaphragm and to reduce his respirations in numbers. If a patient is in a habit of breathing twenty times a minute and is able to reduce his respiration to only ten, and to do this rest breathing for ten or fifteen minutes several times during the day, so that the accumulated time he had devoted to it amounts to two and a half hours, he has saved his lungs fifteen hundred respirations or three thousand excursions, or in five hours three thousand respirations or six thousand excursions.

When one considers that by this method of breathing not only the lungs but the heart also is spared many a movement and energy is thus preserved to a considerable extent, its value must be obvious. According to the latest edition of Howell's textbook on *Physiology* (3), the total work done by the left ventricle at each systole is equal to 20,085 grams centimetre. By reducing this to pounds and feet, it figures about one and a half foot pound for each contraction of the left ventricle. Lawrason Brown estimates that the right ventricle does one half pound of work. This added would make the work performed by the heart about two pounds for each systole. Thus if with each normal heart beat an energy equal to two pounds is exerted, and by reduced and restricted breathing we save the heart two or three

contractions per minute, we spare the heart from 1200 to 1800 foot pound of energy in five hours.

Lastly, diaphragmatic breathing will also cause a better circulation in the lower extremities and abdominal viscera, especially aiding the hepatic function, all of which is so essential for patients who are ordered complete physical rest on a reclining chair or bed.

I have been asked whether women who, for biological reasons, do not use the diaphragm in breathing as much as men do, can adopt this physiological adjuvant. Whether or not it is because of the abandonment of tightly laced corsets that I have had no difficulty in this respect, I do not know. At any rate, I have also the assurance of Prof. Joel E. Goldthwait, of Boston, who has had such a large experience with cases in which he prescribes diaphragmatic breathing in order to correct faulty conditions due to postural or typical orthopedic deformities in women, that he has no difficulty whatsoever in making his female patients use diaphragmatic breathing.

The psychological effect of this method is likewise of distinct advantage. When the tuberculous patient, during the active stage of his disease, is condemned to absolute inactivity in bed or on the reclining chair, he will often become despondent because he has nothing whatsoever with which to occupy his mind. By resorting to this method of respiration he has something to do which will divert his attention, and the more often he does it the more will he improve his condition.

Although we believe that by our spirometric and metabolic tests we have demonstrated that in controlled diaphragmatic respiration there results no air hunger and no increase or accumulation of carbon dioxide, some patients might feel the desire for deep inhalation or a more rapid breathing after the prescribed exercise. The possibility of harm being done by a true or imaginary effort to compensate the air supply can be overcome by teaching the patient to return only gradually to his normal type of breathing. Dr. Martin F. Sloan, the director of the Maple Heights Sanatorium, at Sparks, Md., who has tried the controlled diaphragmatic respiration extensively, uses this precaution of gradual return to the previous mode of respiration. He is convinced that this prevents an acceleration of the respiratory movements liable to counterbalance the effect of the limited movements.

In this short paper I cannot reproduce the many comments on the method which have been made by eminent physiologists and phthisiotherapeutists, but one of the members of this association, Edward Archibald, on learning of my method, stated that it was "a most valuable contribution to the therapy of tuberculosis." One of the greatest European authorities on artificial pnuemothorax and thoracoplasty, my late friend, Christian Saugman, of Denmark, wrote: "I have studied your method with great interest and tried it on myself and was able to reduce my respirations to three and a half per minute without any difficulty. . . . I will employ your method in the treatment of my patients at the sanatorium."

From the reports which have come to me of the results obtained from an extensive trial of this method, I will only mention the one from George Dock, formerly of the Washington University of St. Louis, now of the Barlow Sanatorium, Los Angeles. Dr. Dock says: "I am especially interested in this method because I think you have shown a definite way of lessening movement in the part of the lung most affected as a rule. I look on the improvement of the abdominal circulation as of great importance and believe the psychological element introduced is of no little value. This method is a useful addition to the class treatment of tuberculous patients. The demonstrations and questions raised give many opportunities for learning the many problems and inhibitions of the "lunger." Like all methods that lead to closer cooperation between patient and therapeutist the work has had a distinctly good psychological effect. In various reports I have had the patients give me I find such statements as the following: Helps to relax, quiets the heart, lessens fatigue, increases endurance. I have a very strong impression that the more intelligent the patient the more benefit he is likely to receive from carrying out your adjuvant along with the other necessary measures."

I am not prepared to say that this rest breathing, limited to the diaphragm, may not also help in preventing the greatly feared aspiration pneumonia in the better lung, and perhaps also help to bring about a more rapid formation of fibrous tissue; at any rate, I believe it is reasonable to suppose that such beneficent influence may be obtained thereby. To this end I think it will be good practice to teach the patient the method of controlled diaphragmatic respiration a few days before the operation, and if it is feasible to apply mechanotherapy at the same time by limiting the respiratory movements of the slightly involved apex, it will not be difficult for him to learn to restrict his respiration to the lower portion of his comparatively well lung. When the patient has learned how to use his respiratory function before the operation as a likely safeguard against respiration pneumonia, he will be glad to use it as a therapeutic agent to further safeguard his predisposed apex from invasion afterwards.

Before allowing our patients to resume walking exercises we must see to the strengthening of the muscles of his extremities which may have become almost atrophied from disuse. There is no better means to accomplish this than simple massage, consisting in friction, kneading, tapping, and stroking in the direction of the venous circulation, which any nurse or relative of the patient could easily attend to. Massage rouses dormant capillaries, increases the area and speed of the circulation, furthers absorption, and stimulates the vasomotor nerves, all of which are aids and not hindrances to the heart's action and to nutrition in general. Of course, massage cannot manufacture blood cells or coloring matter, but it can put in circulation those that are dormant in the system. Unless this is done, there results the condition picturesquely described by the poet physician, the late S. Weir Mitchell, as "like the want of circulating money during times of panic, when gold is hoarded and not made use of, and interference with commerce and manufacturing results."

By this therapeutic means we not only improve the flabby, disused muscles, but at the same time help to overcome the anemic condition characteristic of almost all tuberculous sufferers, and before leaving

the subject of massage I would like to tell you the opinions of a few eminent tuberculosis specialists on its value. Edward R. Baldwin and Lawrason Brown, at the head of the Trudeau School at Saranac Lake, are very emphatic about massage being an important adjuvant in modern phthisiotherapy, and one almost neglected in this country. Otis, of Boston, an equally well known expert in tuberculosis, said: "Massage, I believe, is a valuable aid in the postsanatorium rehabilitation of the patient in arrested tuberculosis, and indeed before that period in certain cases."

I have already referred to the value of careful sponging with tepid water at any time the patient has an appreciable rise of temperature, but after he is up and about, like all tuberculous patients, he will be quite susceptible to changes of temperature. Aside from the tonic value to the cutaneous, nervous, and muscular system of judicious hydrotherapy, I do not know of anything which so lessens the susceptibility to colds as the application of cold water. Of course, with one recovering from a surgical operation or one who has never been accustomed to the use of cold water, it is important that precautions be taken to avoid the possibility of chilling the patient. At the beginning the cold water application should be made in the form of an ablution, either in the morning when the patient arises from his bed, or in the evening after he has been in bed for about ten minutes and has become thoroughly warm. If necessary, the bed can be warmed with the aid of a hot water bag, which may remain at the feet of the patient. It is also well to have the hydrotherapeutic arrangement as near the bed as possible. If the bathroom is not situated close to the bedroom, it is best to use a circular English bathtub, about three feet in diameter and ten inches high, half full of water at a temperature of about 105° F. This should be placed near the bed. The second part of this simple hydrotherapeutic arrangement consists of a wash basin full of cold water with a large sponge, placed near the tub on a table of ordinary height. The temperature of the cold water can vary from 40° to 90° F. From 40° to 45° is usually the temperature of the water coming out of the faucet. It is best to begin with the cold water at a temperature of 85° and then go down gradually five degrees every four or five days until a temperature of 40° is reached and borne comfortably. It is always well to have the windows closed and the room warm while the patient is taking his cold water application. If in spite of all precautions the patient should fail to react, the cold baths must be discontinued.

The ablution is applied in the following way: The patient stands in the tub with five inches of water at 105° F.; at the beginning the nurse in attendance, and later on the person himself, takes the sponge soaked in the cold water and squeezes it out first over the back of the neck, then in front over the thyroid, then over the left shoulder, and then over the right, letting the water run down so that the entire body is bathed with cold water. The patient then dries himself quickly, not necessarily very thoroughly, with the aid of a large, rough towel, and returns immediately to the bed. Under the warm cover he will feel warm and the little moisture left on his body will soon dry. Through this procedure reaction is assured, and the patient rarely fails to feel comfortable and enjoy the cold water application. If the head should get wet accidentally, he should dry it thoroughly. This is a precaution the patient should always take whenever he has washed his head. When the system has become accustomed to the cold water used in this way, the patient can safely resort to the application of a needle bath, a shower bath, or plunge.

In regard to heliotherapy, I must confess that in general we have not yet been very successful with the treatment in pulmonary tuberculosis, and in fact a good deal of harm has been done by the injudicious exposure of consumptives to the rays of the sun. The reason of this is obvious when we consider the constant movement of the lung as compared with glands, skin, a fixed joint, or peritoneum and intestines; all these organs are benefited by heliotherapy because they are at rest, or at least at comparative rest. The failures of heliotherapy in pulmonary tuberculosis are to my mind also to be ascribed to the exposure not having been gradual enough. From my own experience, I have reason to believe that would we follow Rollier's method and begin by the exposure of a few inches of the cutaneous system from below upward at graded intervals and duration and limit the application of the rays to such portions of the lung as are greatly limited in their movements by an external restriction, collapsed by artificial pneumothorax, by the section of the phrenic nerve, or thoracoplasty, and only at such times when the patient is doing his rest breathing, heliotherapy or even artificial sunlight may be of great value.

Of psychotherapy in thoracoplasty before and during operation we have already spoken. It is of course of equal value during convalescence and thereafter. When the patient is convalescent he must of course be warned against overexertion on account of his diminished breathing space. He should never walk or work when tired nor to the extent of getting tired, nor when a feeling of dyspnea comes over him. My young colleague, Dr. J. Burns Amberson, formerly of the Loomis Sanatorium, now of Detroit, Mich., has well said: "Like pneumothorax, thoracoplasty in itself does not remove the tuberculosis. The surgeon sets the stage for better healing; and then, under the supervision of the physician, the patient continues hygienic rest treatment until such healing is attained. To neglect this is to thwart the possible good effects of surgery."

In conclusion, let me say, thoracoplasty, if successful, will give the patient a new lease of life and a comparative feeling of well being which he had probably not experienced for many months or years. Well may we physicians be grateful to our colleagues, the surgeons, who are now helping us by their skill to cure many formerly hopeless cases. There is every reason to believe that with the help of thoracic surgery the time may come when we will no longer have to speak of incurable cases of tuberculosis.

Our Social Evasion*

TRIGANT BURROW, M.D., Ph.D.
Baltimore, Md.

It is generally conceded that any man having the choice to be regarded either as a fool or a knave would infinitely prefer the latter classification. We psychoanalysts have thus far been spared the former appellation and we have preserved our self possession fairly creditably against the cries of knavery on the part of our social environment. After all, there is a certain romantic flair connected with the reputation of the gay Lothario or the free lance. But we shall not find ourselves so calm in the face of imputations that challenge the accuracy of our mental processes. I am convinced that our position is edging very near the danger line in this respect and I think it befits us to confront our position very seriously.

As with all progressive ideas, psychoanalysis has from its inception weathered heavy seas of criticism, but the indications are now that as scientists we are seriously paying the price of an unconscious social compromise with popular feeling. The moment has come for us to examine ourselves as a social organization from the point of view of our relation to the social organism as a whole. I am convinced that, unless we take entirely new and fresh ground with respect to the problem of the neurosis as it affects the organismic life of man, we must be content to subside into the rank and file of conventional practitioners who lay no claim to farreaching measures of medical research but who confine their activities to relieving momentarily the locally impaired constitution of their individual patients.

The circumstance which every psychoanalyst knows is that the neurosis of the individual rests in every instance upon a secret family situation. The image fixations with which a patient replaces his natural human relationships and to which he tenaciously holds against all the inroads of reality every psychoanalyst recognizes as the root of the neurosis. In his individual capacity as an analyst it is his endeavor to resolve these obsessive and mentally inbreeding fixations by permitting the patient to enter with him into a quite objective analysis and understanding of these spurious components responsible for his introverted mental state. Every psychoanalyst knows also—though he has as yet not taken practical account of it—that the family of the individual patient is but one small portion of the larger social cluster or aggregate comprising our wider human family in its entirety. This more extensive social organism has its social unconscious also. It has socially its image substitutions as truly as the single person. This social organism is as much under the domination of the mother complex in the selfprotection it fancifully procures for itself under the social image of church, state or economic system as are the individual personalities whom we undertake to analyze in their more obvious because more restricted expression of this same image protection.

As individual analysts we have endeavored to maintain a strictly scientific attitude toward our individual patients. But have we maintained as consistent an analytic position with respect to the personality of society at large? In our exclusive preoccupation with mental processes in their ontogenetic aspects, have we taken into account the study of these same processes as represented in the individual's phylogenesis as a social organism? We have viewed the individual as an isolated part in our complex societal life, but it is my position that we have failed signally to confront this organismic societal life of which the individual is but an isolated manifestation.

It must be obvious to us as psychoanalysts that there is a definite conflict, a marked discrepancy in our position that needs to be brought to the light of analysis. It must be clear that if we continue to blink the facts of our social pathology as of our own part in its processes, we are automatically excluding ourselves from the position of research students holding the wider interests that centre upon a program of preventive medicine with respect to the community as a whole. In any other course this analytic organization becomes an entirely nontechnical gathering composed of physicians who accept quite naively the social complexes surrounding them and who can therefore only sit discussing such complexes, as the newspapers, periodicals and world conferences do, upon a quite manifest and naive level.

In saying this I would like to be understood as speaking not as a theorist but from the ground of definite laboratory investigation of our social complexes through the definite analysis of social or group situations. Actual experimentation with groups makes clear beyond question the wide disparity between the analytic position we occupy in regard to the neurosis as it exists in the individual and the position we hold toward this same manifestation when confronted in its mass or social amalgamations. Technically viewed, the position of the group is identical in its social systematization with the position occupied by the neurotic in his individual systematization. Like that of the neurotic the systematization within the group is most jealously guarded by it. We well know that the motive to the individual neurosis, with its intricate mechanisms of defense, is the private advantage the neurotic unconsciously believes it holds personally for him. But if we will employ a technic that affords a group basis of analysis, we shall find experimental ground to show that the organized group or cluster maintains socially an equally complicated system of defenses and that its motive is not one whit different from the individual motive actuating the neurotic personality. The neurotic fully believes unconsciously in the egoistic images that are the projection of a system that is private and personal to him. Likewise the social group is unconsciously no less a prey to images that are the projection of a system that is wholly esoteric and dissociated.

When we come to confront the indiscriminate social group under the experimental conditions of a social analysis, it becomes evident that such aggregates are socially bound up with and are an integral and con-

*Presidential address before the midyear meeting of the American Psychoanalytic Association, New York, December 27, 1925.

tinuous part of a widespread emotional system extending throughout society at large. Even a quite casual survey makes plain how overwrought and unstable is the temper of the times. Our newspapers amount practically to clinical charts in social psychopathology. But the national consciousness of which these daily bulletins are a record knows well how to confine itself to the mere manifest content of this telltale material of our social mind and to avoid with painstaking accuracy any analytic penetration into the latent content such as would throw light upon its national and international import.

But if we remove a segment, as it were, from the midst of this widespread social organism, if we segregate an integral portion of this social continuum and submit it to the process of an actual laboratory analysis, it is shown that this generic social consciousness is throughout a prey to phobias and obsessions, depressions and elations, inhibitions and compulsions, feelings of reference, grandiose ideas, suspicions of persecution and a hundred other classical symptoms that are the direct counterpart of those with which we are familiar in the individual patient. These conditions, whether expressive of a social mother complex or of a national father imago, may be clearly shown upon analysis to be based upon reactions that are identical with the image projections of the individual. But although, as with the individual, these reactions are kept assiduously repressed and unconscious within our social life, nevertheless it is these psychopathological conditions which analysis reveals to be the real inciting occasions of our political, industrial and economic dissensions as they are the underlying occasion for the more violent paroxysms of our national life such as those we know in the clinical episodes of religious hysteria and of war. Our industrial panics and political crises with their ambivalent phases of excitement and decline represent the equivalent of obsessive states with which we are confronted again and again in the demonstrable cycles of our individual patients. Our frenzied greeds, our national competition and usurpations rest upon definitely compulsive reactions within the national consciousness. Our market inflations and our financial depressions are but the fluctuating mental states that represent the manic and depressive phases of an unstable social cyclothymia.

The superficial and naive explanations popularly assigned as the real occasion for these manifestations —such, for example, as the alleged necessities of territorial expansion, international commercial competition, the urgency of tariff readjustment, race prejudice, nationalism, our economic franchise, the rights of the minority, etc.—all these manifest symptoms are but unconscious rationalizations well calculated to repress from the social consciousness the real underlying occasions of our national neuroses. What is called capitalism, Nordic superiority, bolshevism, fascism, class consciousness, one hundred per cent. patriotism, industrial democracy, our fluctuating ratios of monetary exchange—all these and a thousand more are but mental states which, instead of being treated by us as substitutive manifestations calling for definite analysis and adjustment, are universally accepted as bona fide expressions and their latent meaning remains completely unchallenged in its psychosocial implications.

Far from having instituted a thoroughgoing laboratory analysis of these social states of mind with a view to their basic resolution, in our fictitious social mood we continue still to hold the quite superficial and oldfashioned therapeutic attitude that applies external correctives to these internal conditions. Accordingly, all manner of remedial measures have been resorted to by way of correcting these obvious disorders. Have we not a nationally widespread therapeutic agency represented in prohibition? Have we not everywhere throughout the country the imposing piles of masonry that constitute our churches, our asylums, our penitentiaries and our schools of reform? Nor must we forget our excellent institutions of learning with their munificently endowed chairs for the study of international relations and programs for world peace. Upon an even larger therapeutic scale we have our international programs of disarmament, our peace conferences, our leagues and interleagues of nations. But in all this evasive attitude of the popular mind how does it happen that we as an organization give our assent to such superficial measures of meeting the condition? How does it happen that we give our sanction socially to superficial measures of psychotherapeusis to which we would not think of subscribing in the individual case because of what Freud has shown in the individual case to be the utter futility of dealing locally and superficially with a condition that is deepseated and that affects the constitution of the individual organism as a whole? The category of knaves would indeed be most delectable in comparison with the fool's paradise in which we unconsciously place ourselves in this wholly esoteric and arbitrary inconsistency.

It is significant—this discrepancy between our analytic attitude as it confronts the individual and our completely nonanalytic attitude as we confront this same neurosis in its collective manifestation. As psychoanalysts we would not think of applying moral stringents to our neurotic patients by inducing them to mend their ways under threat of withdrawing from them their favorite amusements. It would not occur to us to attempt to intimidate them with punishment or to decoy them with secret promises of gain. These older therapeutic measures that applied the rod or conferred the crown we have long done away with. Yet the social consciousness of which we ourselves are a part still adheres to the superficial program of correctives that actuated the older schools of psychotherapy prior to Freud.

It need hardly be pointed out that for practical laboratory purposes our own psychoanalytic concern must necessarily restrict itself to our own psychoanalytic group. For in the absence of a social analysis the organization composed of our own members is in no different case from that of the social organization elsewhere. Naturally it is our tendency not to see our own embroilment any more than the social group elsewhere or the neurotic individual sees his and for precisely the same reason—namely, that it is our own embroilment. We are all a daily witness that the neurotic exercises over his neurosis the private prerogative of secret repression and evasion. But as a social group we have not seen that we likewise exercise over the collective involution which we ourselves share socially the same automatic evasion and defense. In dealing with our neurotic patients we do not argue

or discuss with them their unconscious situation. No more may we meet our own unconscious situation with argument and discussion. We analyze the neurosis comprising the circumscribed system of the neurotic individual. We must also analyze the neurosis comprising our own social systematization. We have not dealt with this social condition analytically simply because, being a social condition, there is involved analytically our own participation in it. But if we are to proceed with the development of our work with logical fidelity, we cannot continue to indulge our present social evasion nor escape the wider social implications inherent in our analytic principle of procedure. In scientific honesty it becomes necessary that the social organism comprising ourselves shall submit itself to a process of analysis that is as thoroughgoing and uncompromising as the method of analysis we have learned through Freud to apply to the individual patient.

It would be very natural to suppose that what is here said in respect to our subjective needs may be approached in the calm and detached spirit with which we view the factors entering into the material of our objective investigations. But in this interpretation we are again adopting a position that is the parallel of the neurotic individual who prefers to take a discursive and theoretical stand toward his neurosis in order to evade his individual analysis. To adopt a theoretical interpretation of our own subjective situation as a socially organized unit is likewise to evade the need of the subjective analysis of our own social organization. The laboratory of psychoanalysis cannot be the conventional laboratory in which we stand as onlookers of processes in front of and outside of ourselves. On the contrary, in such a laboratory we ourselves become the material under investigation at the same time that we become the observers of such material. For in a social analysis the elements under examination are the elements of our own social tissue. We become as definitely the unwilling and refractory subjects of our own experimentation as the refractory and unwilling subjects we confront in our laboratories of animal experimentation. It is therefore a far cry from a position of mere theory to the actual condition of a laboratory analysis, and the difficulty lies not so much in the impossibility of a social analysis as in the unwillingness of the individual to let go his own individualism and participate in this social condition of selfinquiry.

As a result of experiments in group analysis the conclusion is for me unavoidable that, in the absence of an inclusion of the individual's phyletic substrate as a social organism and of the social factors inseparable from this wider setting, we have failed to compass the true meaning of our individual analysis and have faltered seriously in respect to our findings. It has become clear to me that our private basis of analysis has entailed errors in three essential respects. First, we have unwittingly read into our private interpretations factors for which there has often been lacking sufficient scientific warrant; second, we have failed to take account of many factors for which there has been ample scientific authority; and third, in our attitude toward factors which were demonstrably present we have too frequently placed upon them values and interpretations which are out of all relation to their biological significance and setting. With such findings before me it is naturally not possible for me any longer to regard as scientifically conclusive a program of analysis which restricts itself solely to our individual complexes and does not include a consensual laboratory investigation of the phyletic or social complexes of which the individual is a part.

In papers read recently in Homburg and elsewhere I have attempted to define in detail the logical ground for this social and consensual basis of analytic inquiry as a necessary condition for placing our observations within the mental sphere upon as sound a laboratory basis as the observations we habitually bring to the laboratories of biology elsewhere (1). As in our observation of material in the laboratories of biology we demand a consensus of perception among the laboratory observers, so there is equally demanded a laboratory consensus of perception for the clear determination of the data composing the field of our mental observations. It is my contention that our observations rest today upon a purely private and esoteric basis of judgment. If anyone is disposed to doubt this, let him but recall how frequent is the circumstance in which a condition offers in the view of one analyst one interpretation while in the view of another the same condition is interpreted in a totally different way. Or, if further proof is required, consider the frequent disparity in the expert psychiatric testimony offered in our courts of law. We are all aware that it is a quite usual procedure to find two groups of psychiatrists—both of them composed of men of undoubted ability, training and scientific sincerity of purpose—confronted with identical clinical material and yet interpreting that material upon diametrically opposed bases of judgment. The result is that in the view of one faction an individual is judged as hopelessly insane and in the view of the other as a quite normal individual. When there will have been established a definite laboratory criterion of practical observation in the estimating of mental and emotional data such shocking discrepancies in the positions of scientific men submitting testimony before the social community will of necessity be precluded.

There is not the opportunity here to develop this thesis more fully. Suffice it to say that our resistances to a laboratory inquiry into our own social complexes will necessarily be very great. In the laboratory undertaking of my associates and myself, which after all is in its mere infancy, the resistances encountered by us singly and collectively have seemed at times almost insurmountable. But this is really no matter. We cannot maintain the position of scientists and hesitate before the implications of our own scientific position. However we may balk in the face of the need to examine our own mental processes, there exists nevertheless the situation in which the individual psychoanalyst is involved socially in exactly the same unconscious processes as characterize the unconscious of our individual patients.

In face of the arduous difficulties that have already confronted us as individual psychopathologists, a thesis that involves fresh obligations of endeavor is not a welcome thesis, I know, and in stating it I find myself in a quite novel position. From the very inception of this association my interest has been

closely identified with the interests and endeavors of the physicians composing it. But, due to accidents which have fashioned for me a new angle of observation into our common problems, certain conceptions have been forced upon me which necessarily diverge from the restricted position that has been for these many years our common ground of outlook. I should indeed be acquitting myself in the rôle of both fool and knave were I not sensible of my initial obligations to the conceptions underlying the work of this organization. But upon the closer scrutiny acquired through an extension of our analytic basis of procedure it will be found that the emphasis upon the analytic conceptions which we have so long shared and the emphasis to which recent years have led me need not, in essential respects, be lacking in scientific accord. Whatever difference may appear between our present outlooks is due, I feel, only to the circumstance that there has not been the opportunity for an analysis among the members of this group on the altered basis to which I refer. My feeling is that subsequent experimental contacts on the part of this group with the group technic with which my associates and I have in the last years been occupied must ultimately enlist the interest of this organization and that the actual laboratory application of our common experience to our social problems will become as necessary a supplement to the individual analysis that now engages the interest of this association as it has become the necessary supplement to the analytic interest of my associates and myself.

Syphilis in Its Relation to Iritis and Other Eye Conditions*

GEORGE HUSTON BELL, M.D., F.A.C.S.

New York

In the earliest stages of acquired syphilis anomalies of the pupillary reaction are noted frequently, and later on the Argyll-Robertson phenomenon is sometimes seen. Also when patients come to the ophthalmologist complaining of headaches, vertigo, eyestrain and double vision, it is found that they are sometimes suffering from brain syphilis, tabes, general paresis, or disseminated sclerosis. My experience teaches me that the eye is more frequently involved in the early invasive stages of syphilis than was formerly supposed. It will not be possible in the brief time allotted for this paper to give a detailed account of all the various syphilitic affections of the eye, because syphilis attacks the eye from all angles. Once a person is infected with the Spirocheta pallida, neither eye is immune from the ravages of the disease—not even the eye *in utero.*

I shall mention in detail only a few of the outstanding diseases of the eye which you may have to treat; the rare syphilides may also be encountered.

HEADACHE AND EYESTRAIN

These are important symptoms. Headache is one of the earliest symptoms in infected persons and one of the most frequent. When patients complain of nocturnal headaches which keep them from sleeping, and also complain of a general fullness in or about the head, it is generally a meningeal involvement. It should arouse suspicion and cause one to have a Wassermann blood test made.

Of course, headaches may be due to various other causes, such as errors of refraction, focal infections, food intoxications, excessive stimulation from alcohol or tobacco, muscular asthenopia, and so on.

*Read at the annual meeting of the Surgical Corps of the Lehigh Valley R. R., at the Hotel Pennsylvania, New York, February 20, 1926.

DIPLOPIA

A patient comes to the general surgeon complaining of double vision long before any paralysis of the exterior ocular muscles can be detected. You will observe that the diplopia increases as the object is moved to the side of the paralyzed muscle. There are two kinds of diplopia, lateral and vertical. If the third nerve is affected the images are crossed and we have a diverging strabismus. If the sixth nerve is involved we have an homonymous diplopia and a converging strabismus. If there is a difference in the height of the images, the superior or inferior rectus, or the superior or inferior oblique may be involved. If the entire trunk of the third nerve is involved, the eye diverges, there is ptosis, the iris is widely dilated and accommodation is paralyzed. Paralysis of the exterior ocular muscles may be followed years later by tabes, disseminated sclerosis and paretic dementia (Manthner).

According to de Schweinitz, fifty per cent. of these cases are due to acquired syphilis. Certainly all should have a Wassermann test. Of course, local infections—the "Three T's," sinus trouble and acute infectious diseases—must always be considered in making a diagnosis. Sometimes it is found that there is a mixed infection.

Recently a woman, aged fifty, came to me with double vision and a ptosis of one eye. The Wassermann test was made and found to be positive. She also had a "dirty mouth." I put her on antisyphilitic treatment and my "reform diet," but she made little progress until I had three infected teeth extracted. One of these teeth had a pus bag hanging from the root of it. She has now recovered entirely. Of course I kept up the antisyphilitic treatment. The

prognosis is good in these extraocular muscle cases if taken early and the patient is not too old.

VERTIGO

This is sometimes the first symptom complained of by patients with ocular palsies and should always arouse suspicion. Of course, vertigo may be due to eyestrain, sinus trouble, diplopia, oral sepsis, diseases of the internal ear or intestinal toxemia. Sometimes a full dose of castor oil will help to clear the diagnosis.

PTOSIS

This is another symptom of acquired syphilis which the general surgeon may have to see. If the drooping eyelid is raised, it will generally be found that in all probability there is diplopia also. Of course, ptosis may be due to some other condition, but acquired syphilis is one of the outstanding causes of the trouble.

Disturbances of the cranial nerves are always suggestive of cerebrospinal syphilis. Recently I had a case of double ptosis in a woman aged twenty, with paralysis of most of the exterior ocular muscles. The Wassermann in this case was negative, but she had all the earmarks of hereditary lues. She had the peculiar physiognomy of syphilis, consisting of coarse, flabby skin, scars of old fissures at the angles of the mouth, a sunken bridge of the nose, roof of the mouth highly arched, and the typical Hutchinson teeth. What more would you want for a diagnosis? We looked her over for the "Three T's" also, and gave her vigorous antisyphilitic treatment. She is still under observation and is improving.

SYPHILIS OF THE IRIS

According to Duane, acquired syphilis is by far the most frequent cause of iritis. That certainly corresponds with my experience at the New York Eye and Ear Infirmary, and it may be added that iritis is one of the most frequent symptoms of acquired syphilis. There are several varieties. The clinical manifestations vary greatly. The symptoms may be those of ordinary acute iritis of the plastic type or the serous type or the true syphilitic type—iritis papulosa. In plastic iritis there is a deep ciliary infection, forming a zone of short vessels around the corneal margin, with cloudy, aqueous swelling and discoloration of the iris, irregularity in the shape of the pupil, which is generally contracted, tension normal, exudation in field of the pupil—photophobia, lacrimation, defective vision and great pain. The eyeball is also tender to pressure.

Of course, it is not necessary to have all these symptoms at first. Pain is generally what causes the patient to consult a physician, and then redness of the eyeball may alarm him. In the serous type there are all the symptoms mentioned above and in addition there are punctate deposits of exudation upon the posterior surface of the cornea, and sometimes in these types there is elevation of tension. This inflammation generally extends to the ciliary body and the choroid.

In true syphilitic iritis, in addition to the above symptoms, there may be seen in the iris one or more distinct, yellowish red, nodular elevations, varying in size from a hemp seed to a pea. These deposits may be found either in the sphincter region or at the periphery and they have a tendency to coalesce. The prognosis is good in the first two varieties, but none too good in the papular syphilides, as the eyeball sometimes goes on to an atrophy.

DIAGNOSIS OF SYPHILITIC IRITIS

The diagnosis of syphilitic iritis will of course be based upon the history of the case, the symptoms, and the Wassermann reaction. In the last few years the diagnosis of syphilis has become more and more dependent upon the Wassermann reaction and there has been a tendency to neglect those clinical signs so characteristic of the disease. But should every iritis which has no characteristic marks be called syphilitic, simply because it occurs in a syphilitic person? Often, to be sure, this would be right, but still a syphilitic person may acquire an iritis from some other source or a toxemia from some other cause. At least he should be given the acid test for the "Three T's," which stand for infected teeth, diseased tonsils and toxemias of the gastrointestinal tract. I presented a paper on my "Three T's" at the meeting of the American Medical Association, at Atlantic City, in June, 1919. I said at that meeting that a dirty mouth is one of the greatest menaces of the human race, and that oral sepsis is the arch enemy of us all. Your patient may have infected teeth, diseased tonsils or he may have an intestinal toxemia from food intoxication; in other words, he may be suffering from some toxemia entirely foreign to his syphilis, or he may have a mixed infection. I lay great stress upon checking up the focal infections, the "Three T's," in every case of syphilis of the eye. Of course, the possibility of gonorrhea must not be lost sight of, as it is prevalent in those suffering from syphilis.

SYPHILIS AND ORAL SEPSIS SIDE BY SIDE

To illustrate what I mean by a mixed infection, I will cite a case of plastic iritis in both eyes, which I showed at the New York Academy of Medicine in 1917.

A patient had a four plus Wassermann and fourteen badly decayed teeth. I admitted him to my service at the New York Eye and Ear Infirmary, treated his iritis locally and started him on inunctions of mercury. We began pulling his decayed teeth and at the end of five days we had extracted fourteen of them. Following the extraction of his teeth the improvement was so marked and rapid that after seven inunctions I decided to stop them to see if the iritis would continue to improve. The patient made a rapid recovery and left the hospital at the end of four weeks with normal vision. He gained fourteen pounds in weight in the first nine weeks that elapsed after the teeth were extracted. I treated him for constitutional syphilis later on, but I wanted to see what would happen after the removal of those septic roots.

TREATMENT OF SYPHILITIC IRITIS

Local treatment should consist of hot applications at frequent intervals. Leeches should be applied to the temple for pain. A one per cent. solution of atropine should be dropped in the eye every three or four hours. The pupil must be kept dilated. A stronger solution of atropine may be used if necessary, and the tension watched. A five per cent. or ten per cent. solution of dionin on account of its

lymphagogue and analgesic action may be used. Rest in bed should be insisted upon if possible, and smoked glasses. The constitutional treatment should include the use of neoarsphenamine. Engman prefers arsphenamine. Between injections, there should be inunctions of mercury. As Engman says, "mercury has been the savior of the human race in combating this plague." Of course, we use the reform diet and all foci of infection must be cleaned up. Drinking and smoking are prohibited, also tea and coffee.

INTERSTITIAL KERATITIS

Etiology.—In a great majority of cases, inherited syphilis is the cause of interstitial keratitis. A small percentage of the cases are due to acquired syphilis. Tuberculosis may be a cause also, and there may be a mixed infection.

Symptoms.—Interstitial keratitis begins as a diffuse haziness generally in the centre of the cornea of one eye, with congestion, irritability of eye and dimness of vision. The opacities consist of dots in the parenchyma of the cornea. In a few weeks the whole cornea has become opaque and we now have the ground glass cornea. The slit lamp, demonstrating the corneal haze, may be resolved into very fine points of greyish color. At this stage there is ciliary congestion, iritis; a great deal of pain and photophobia. The bloodvessels derived from the ciliary vessels are thickly set in the layers of the cornea and produce the dull red color—the "salmon patch" of Hutchinson. Sometimes these patches extend all over the cornea, producing a cherry red effect.

Fortunately ulceration rarely occurs. After a varying period of weeks or months, the other cornea is attacked. Vision may be reduced to light perception. In the course of time, varying in accordance with the treatment, the cornea begins to clear. It is a slow process at best. Secondary glaucoma may develop and tension must be watched. The diagnosis is easy. The subject generally presents a combination of physical defects, typical of the disease. The stature is dwarfed, there is a peculiar physiognomy, coarse, flabby skin, scars and prominences on the forehead, sunken bridge of nose, roof of mouth highly arched, and Hutchinson's teeth.

Strange as it may seem, we find Wassermann negative in about twenty-five per cent. of these cases. Fortunately the prognosis is favorable, although I have seen some cases most refractory.

TREATMENT

Notwithstanding the signs of hereditary lues, the patients should be given the Wassermann test. A long continued course of mercury is indicated. Hutchinson preferred mercury and chalk with opium, if necessary. We use neoarsphenamine as we feel it shortens the duration of the disease. Between the neosalvarsan injections we give mercury and chalk or inunctions of mercury and syrup of iodide of iron as a tonic.

It is most important to look these children over for the "Three T's." Nearly all of these children have defective teeth. Some of them, I find, have never used a toothbrush. Diseased tonsils and adenoids block the postnasal space; moreover, their diet is always bad, with an excess of sugar and sweets and soft carbohydrate foods. Surely they all need the reform diet.

After the acute symptoms subside, they should have plenty of fresh air, sunshine, and exercise, wearing, of course, smoked glasses.

SYPHILIS OF THE EYELIDS

Chancre and gummata.—Both are rare diseases. Rodent ulcer and epithelioma have some points of resemblance to chancre, but the former two occur late in life. When the gumma involves the tarsus it is known as tarsitis syphilitica.

Syphilis of conjunctiva.—Occasionally an obstinate conjunctival inflammation, with little or no secretion, is encountered in syphilitic patients. Also one may see chancre, papillary syphilide, or mucous patches. All are rare diseases.

Syphilis of lacrimal apparatus.—Constitutional syphilis rarely attacks the lacrimal apparatus primarily, but sometimes it does later on. Diseases of the lacrimal apparatus are also seen in inherited syphilis.

Syphilis of the sclera.—There may be an episcleritis and a gummatous infiltration of sclerotic. Sclerokeratous iritis is nearly always due to syphilis; occasionally it is due to tuberculosis. Syphilis may involve the whole uveal tract in one eye or both simultaneously.

Syphilis of choroid and retina.—These are associated, even when occurring alone; the treatment is the same. The eyeground should be examined from time to time. In no other condition is vigorous and prompt antisyphilitic treatment more desirable. Syphilis of the retina or chorioretinitis must be considered a serious condition. If treated early, the prognosis is fair. At best there is usually some impairment of vision.

Syphilitic papillitis or chocked disk.—This requires prompt specific treatment—general measures such as reform diet, smoked glasses, rest in bed, and hot applications to the eyes.

ATROPHY OF THE OPTIC NERVE IN SYPHILIS

Several types are met with, as follows: 1, primary atrophy or tabetic atrophy; 2, secondary atrophy; 3, postpapillitic atrophy; 4, retinitic or choroidal atrophy. Syphilis of the lens is seen only in patients suffering from inherited lues. Syphilitic periostitis of the orbit is rare. It may occur in a gummatous form, in which case there would be an exophthalmus.

CONCLUSIONS

All patients with any disease of the eye should have the Wassermann test. The details of the eyeground should be studied carefully in all cases of acquired syphilis. Syphilis should be looked upon as a chronic constitutional disease and treated as such.

In obscure conditions of the eye, the negative Wassermann is often misleading. In order to confirm the diagnosis it may be necessary to resort to an examination of spinal fluid. If the Wassermann is three plus or four plus the diagnosis is confirmed; if it is negative, with characteristic symptoms, the patient should have specific treatment just the same. If we suspect tuberculosis, test should be made for it. If positive, tuberculin can be given subcutaneously while giving inunctions of mercury. They work very well together.

All patients should be given the acid test for the Three T's and placed on the reform diet. I cannot

go into the diet at this time. You will find it in the MEDICAL JOURNAL AND RECORD of March 5, 1924.

The most important factor in congenital syphilis is social hygiene—prevent the marriage of syphilitic individuals.

Acquired syphilis is one of the outstanding health problems of the day—which means periodical health examinations of all patients. I therefore hold that it is just as necessary for the ophthalmic surgeon to get his house in order before subjecting his patient to a major operation upon the eye, as it is for the general surgeon to clean house, and that is the reason why we always insist upon a Wassermann test before operating.

The three great therapeutic agents, outside of antisyphilitic treatment, are: 1, rest for the patient; 2, removal of all foci of infection, and 3, reform diet.

Complete rest from business worries and cares, especially when syphilis affects the cerebrospinal system; but of course the patient must have exercise.

The action of all drugs used in the treatment of syphilis will be enhanced by the three great prophylactic remedies.

40 EAST FORTY-FIRST STREET.

Relationship of Ophthalmoscopic Pictures to Arterial Disease*

S. A. AGATSTON, M.D.
New York

In the presence of normal organs, longevity of man depends on the condition of his arteries. In preventive medicine our attention must be centred on preserving the arterial system. Early recognition of arteriosclerosis is, therefore, an important factor. Blood pressure, while indicative of arterial disease in the majority of cases, does not always define the condition of the patient's arteries, as blood pressure may be functional, or transient. On the other hand it is possible to have arterial disease without any elevation in blood pressure.

Elsewhere in the body the arteries can be felt, but in the eye they can be seen. The importance of studying the arteries in the fundus cannot be overestimated. The majority of internists do not avail themselves with sufficient frequency of this valuable source of information. I might say that those who make a routine examination of the fundi do not study the arteries closely enough to appreciate the variety of pictures corresponding to the gradual progress of arterial disease.

I have discovered no new signs, I am merely reporting my observations of fundus conditions in correlation with cardiovascular disease. These observations were made on a large number of patients in hospital and private practice. When hypertension is present without change in the retinal arteries we are dealing with hypertension which is either functional or toxic. Prognosis as to condition of the arteries is good.

I do not believe that it is possible to have general arteriosclerosis without some change in the retinal arteries.

The following are the changes that we notice in arteries, undergoing the process of sclerosis:

1. White reflex from the large trunks of the arteries. This must be differentiated from juvenile reflex. In the latter, there is a dazzling of light, which extends into the spaces between the bloodvessels, and is also very marked around the disk and macula. Juvenile reflex is rarely seen after the age of thirty years. In arteriosclerosis the reflex is limited to the arterial trunks.

2. The reflex gradually becomes more intense until the arteries assume a wirelike appearance. We also note the pressure effect on veins as the artery passes over them. A sclerotic artery passing over a vein causes an arrest in the blood flow, resulting in ampulla formation on the distal side and an attenuation of the vein on the proximal side. A vein passing over an artery shows attenuation at the crossing.

3. The next change in order is unevenness and attenuation of the arteries giving the calibre a slightly beaded appearance. The arteries are generally more pale than normal. The smaller branches show a tendency to beginning tortuosity. I might mention here that tortuosity of the large trunks is not pathological and may be congenital. Dilatation of large veins followed by tortuosity is an early sign of choked disk.

4. Small branches become markedly tortuous. This is most apparent in the region between the disk and the macula, in which region the small veins also become markedly tortuous.

5. Small hemorrhages, which are frequently found at the terminals of small arterioles or veins. Small exudates, which are fatty degenerations of the hemorrhages or serofibrinous exudates. Sometimes hemorrhages may be large. The macula may show a chorioretinal atrophy with a mottling of pigment.

6. Perivascular connective tissue changes, characterized by white marginal lines: also blocking or obliteration of some of the very small arteries, which are then replaced by white strands of connective tissue.

7. Edema of the disk is usually a late sign, but hyperemia of the disk may appear early. Papilloedema of arteriosclerosis shows only slight elevation. Blocking of the central artery, or vein, may occur before the formation of small tortuosities. Sclerosis of large trunks is frequently accompanied by sclerosis of the chorioidal bloodvessels. This condition is associated with reduction in acuity of vision, caused by a low grade retinal atrophy and atrophy of pigment epithelium. The appearance of the retina is that of sharply defined tesselated fundus, in which the islands of chorioidal pigment and chorioidal bloodvessels are clearly outlined: the disk shows a yellowish pallor.

Pathology of the large trunks only is frequently unrecognized and is not generally accompanied by high blood pressure. The latter seems in proportion to changes in the small branches.

The average blood pressure, corresponding to

*Read before the Harlem Medical Association on November 4, 1925.

change No. 1, is 150 or under; No. 2, 170; No. 3, 180; No. 4, 190 to 200; No. 5, 200 or over. In patients with a fully developed picture of arteriosclerosis, hypertension is frequently too high for the sphygmomanometer to record. These figures are not always absolutely correct, but it is possible to estimate the blood pressure in most cases. Patients with advanced arteriosclerosis may have much lower pressure after a severe illness, cardiac disease, asthenia, starvation, or rest in bed. It is natural to suppose that the cerebral arteries have changes similar to those of the retinal arteries. Just as we can have blocking of the central artery, causing ischemia of the retina with atrophy of the retina and disk, resulting in total blindness, so we can have blocking of a cerebral artery, causing softening of the brain, resulting in paralysis. Thrombosis of the central vein causes a very marked hemorrhagic retinitis. A similar accident may occur to a cerebral vein, resulting in cerebral hemorrhage causing an attack of apoplexy.

These accidents to cerebral and retinal bloodvessels may occur in the absence of any high blood pressure and before arteriosclerosis is evident in the small arterioles. In fact high blood pressure is more likely to be associated with thrombosis in small branches giving rise to less severe symptoms, whereas a low blood pressure is probably the cause of thrombosis in the larger trunks, owing to insufficient *vis a tergo* through diseased and narrowed arteries. This would explain the frequency of hemiplegia in comparatively young patients without high blood pressure. Albuminuric neuroretinitis, with a good deal of exudate around the disk and macula, is not always accompanied by high blood pressure, unless the patient also shows advanced arteriosclerosis.

In eclampsia we may have neuroretinitis with detachment of the retina and high blood pressure, all of which may gradually disappear with hardly a vestige of the condition, when the patient makes a full recovery. In other cases of eclampsia we find advanced arteriosclerosis of the retinal bloodvessels, with persistent high blood pressure following the attack. Diabetes may be accompanied by retinitis, without marked changes in the retinal arteries.

All this would point to the possibility of retinal change caused by toxemia, with transitory spasm of the arteries, which have not undergone any marked sclerotic change.

Acute glomerulonephritis is not accompanied by any retinal manifestation, unless chronic nephritis had existed previous to the acute attack.

There are really two forms of the socalled albuminuric, or renal, retinitis. One of toxic origin, with active parenchymatous nephritis, the other of arteriosclerotic origin with interstitial nephritis. In the latter kidney function is in proportion to the stage of progress of arterial disease. In this form prognosis as to duration of life is much more favorable.

In the first form exudates constitute the predominating picture, while in the other form advancing changes of the arteries, previously described, stand out most prominently.

Proficiency in reading the fundus pictures comes with constant practice. Change in the retinal arteries may be the only objective sign of arterial disease in the incipient or even somewhat advanced stage. In the absence of subjective symptoms the ophthalmologist is frequently the first to discover the presence of arterial disease, with or without hypertension.

140 West Seventy-ninth Street.

Idiopathic Paralysis Agitans*

Report of a Case in a Man Thirty-Five Years Old

THEODORE C. FONG, M.D.
Washington, D. C.

I shall first endeavor to give a brief résumé of this disease. This is a condition which one might expect perhaps to meet with more frequently in a hospital of this type and size, yet a review of the hospital records resulted in the discovery of only three cases. The first of these patients was discharged voluntarily from this hospital; the second was one with a definite etiological history of encephalitis and the man later died from an intercurrent disease; the third case was of idiopathic origin occurring in a man of seventy-two, who also died from an intercurrent infection. Since this article was written, five other patients with affections of postencephalitic origin have been admitted to this institution.

Definition.—Paralysis agitans, shaking palsy, Parkinson's disease is a disease usually of later life, characterized by peculiar tremors, rigidity, attitude, expression and gait. It is not a common disease and has not until recently any definitely recognized anatomical basis. It comprises about one per cent of all nervous diseases.

History.—This disease was at first clearly described by Parkinson (1) in 1817 in his famous thesis on "Shaking Palsy." He described it as "an involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forwards, and to pass from a walking to a running pace; the senses and the intellect being unimpaired." It was subsequently dwelt upon by various writers, Todd, Trousseau (2), Romberg (3) and many others. It was not until thirty or forty years later that an exhaustive clinical picture of this disease was made by Charcot (4).

Etiology.—The age at which this disease occurs is rather significant, the majority of these patients being between fifty and seventy. Erb (5) states that the greatest number of cases occur in the sixth decade of life. Younger persons and those in middle life have also been known to have had paralysis

*Read before the Clinicopathological Society of St. Elizabeth's Hospital, Washington, D. C., February, 1925.

agitans, but in most instances, it was a syndrome which followed some other disease, as poliomyelitis, encephalitis, or syphilis. Stearns (6) reports a case of idiopathic origin occurring in a girl of twelve. It is twice as common in males as it is in females. Race is no factor in its etiology, although it appears to be more prevalent in some nationalities than in others. Dana (7) found it oftenest in New York among the Irish, Polish, and Germans. It is thought that heredity plays some small part in its origin, but this fact is not definitely determined. Overwork, emotional conditions and psychic and physical trauma in some cases bring a latent paralysis agitans to the foreground. Arteriosclerosis is thought to be a chief factor in bringing about the presenile syndrome of paralysis agitans.

Symptoms.—The prodromal period or stage of invasion varies from one to three years. The disease is insidious in onset. Among the rather characteristic prodromal symptoms are irregular pains of sharp character in the extremities where the motor disturbances first make their appearances. These pains usually cease as the disease advances. Paresthesias and gastric distress with diarrhoea may occur; general malaise with headache, sweating, mild vertigo, palpitation, sialorrhea, anxiety and excitability are also symptoms which may occur during the prodromal period.

Jelliffe (8) classifies the symptoms into three groups:

1. "The main group of sensorimotor disturbances, varying in intensity and location.
2. A number of sensory, vasomotor, trophic, and secretory disturbances.
3. Psychical symptoms which are variable and which are possibly unrelated to the condition itself."

The sensorimotor disturbances consist of increase of muscular tonus, with rigidity, and resulting contractures and motor disturbances, with tremor, compulsory gait, forced attitudes, forced movements and absence of facial expression. An increase in the muscular tonus is a fundamental feature and, as a result of this increased muscle tonus, there follows the rigidity, masklike countenance and contractures. The increase of muscle tonus is usually an early sign of the affection and together with tremor are the two most typical symptoms; associated with the hypertonus and rigidity, there is slowness of motion and a steadily increasing stiffness, together with retardation of the motor impulses.

The situation at the onset varies considerably. As a rule, the symptoms are first manifested on one side only of the body, and are usually more severe on this side, a condition which may last for years. As an example, in a rather marked case, the rigidity may involve the muscles of the neck and spine, the patient assuming a stooping posture, the head being flexed, the face stolid and masklike; the arms are pressed against the body, the elbows flexed, the wrists extended and the fingers usually flexed at the metacarpalphalangeal joints and either flexed or extended at the other joints; the legs are usually flexed and adducted. Any group of muscles may become involved though the arms and legs, together with the facial muscles, are the ones most usually affected. At times ptosis occurs, or the patient has considerable difficulty in opening his eyes after closing them. Because of this stiffness of the ocular muscles, reading becomes difficult in the more advanced cases. Ocular palsies may result; slow pupillary reactions are also found. If the laryngeal or pharyngeal muscles are implicated there results a retardation of speech; and these affections become more marked with the progress of the disease so that in time the patient may be unable to talk or swallow. The speech is usually described as slow and monotonous. This hypertonus and rigidity is sometimes associated with the usual reflex signs of pyramidal tract involvement, the reflexes being normal or else slightly exaggerated, and usually there is no Babinski, clonus, Oppenheim, etc., unless there be a complication.

The gait is rather characteristic of the disease, being slow, shuffling or festinating. (Festination is the term applied to a peculiar gait which may be described as the slow run with the body and head in advance of the legs.) However, the gait may be normal for several years after the initial onset.

Tremor is the typical outward manifestation of the disease and this in the majority of cases seems to be the primary sign, although, vasomotor signs are usually present before this is noted. This tremor is characterized by the uniformity of its excursions, which are, at first, small, slow and rhythmical. These tremors average from four to seven per second, according to the group of muscles involved. These movements are mostly coarse although they vary. When this tremor affects the hand, it gives rise to the pill rolling movement characteristic of the disease.

The muscles involved in the early tremors vary considerably, but usually the upper extremity is involved before the lower, the hand in particular, some writers claiming the left more than the right. The reason for this is unknown. The tremors of the fingers consist of flexion and extension, abduction and adduction; those of the forearm, flexion and extension, pronation and supination. The movements of the legs which are affected to a less extent and less frequently than the arms, consist of flexion and extension. With the progress of the disease the tremor becomes more widespread and there is usually a disproportion in the severity, a hemiplegic type of onset and persistence is rather frequent; monolimbic types do sometimes occur. The tremor usually disappears with sleep, but in the more advanced cases the tremor may become so continuous that it ultimately disturbs the patient and causes exhaustion. The tremor tends to be decreased by active exercise; emotion and excitement increase it, touching the affected limb or part may temporarily cause the tremor to cease. Statistics show that tremor may be absent in as high as twenty per cent. of cases, i. e., in the type known as paralysis agitans "sine agitatione."

The disturbances of equilibrium are manifested as follows:

The patient rises with difficulty, pauses for a while, the body and centre of gravity is tilted forwards and he advances with slow, short steps; this movement may change into a forward running gait-propulsion. The patient may keep on until he runs against something or seizes upon some support to stop himself. This festination may be initiated by

giving the patient a forward push. In rare cases one sees the opposite gait, a running backwards "retropulsion." Lateropulsion also occurs, but is rare; in this the patient runs sidewise.

The secretory symptoms are hyperidrosis, increased salivation, polyuria and occasionally diarrhea. Sialorrhea is the most important of these. Among the vasomotor changes are cyanosis, tachycardia, alteration of temperature and dermographia. Trophic changes involving the skin occur also but are rare.

The psychic disturbances (9) consist of emotional depression, agitation and psychic pain; anxiety, hallucinations and delusions of paranoid nature or concerning bodily states as well as varying defects of memory with very slight mental confusion. These psychic manifestations may precede the neurological signs and thus lead to mistaken diagnoses.

The sensory symptoms include pain, thermal and tactile disturbances but are not characteristic features of this condition. The early pains are usually fleeting in character; anesthesia, paresthesia and hyperesthesia are found occasionally but not invariably. When present they are usually indicative of some lenticular or thalamic involvement.

The reflexes are not markedly altered although there is considerable variation. In some cases signs of pyramidal tract involvement are found.

The laboratory findings in the idiopathic form are neither definite nor constant. Examination of the blood is essentially negative, the cerebrospinal fluid is likewise negative, and the urine is negative with the exception of a polyuria in some cases. The urine may show at times a phosphaturia.

Prognosis.—This disease is incurable, there is a gradual advance, and in a few cases there are periods of improvement. Some cases come to a halt and the cases taking this course are believed to be of luetic origin. Remissions and exacerbations are common. The course in the arteriosclerotic cases is usually long drawn out. Excitement and emotion increase the progress of this disease. There are no cases known where recovery has taken place. The patient becomes bedridden and death is usually due to some intercurrent infection. The duration is from eight to ten years; it may be shorter or longer than this but rarely over twenty years.

Differential diagnosis.—The diagnosis of the classical Parkinsonian type is rarely difficult, provided some of the cardinal symptoms are present, the posture, gait, masklike expression and tremor being so characteristic that the disease is almost unmistakable. The diagnosis is only difficult before the development of these symptoms and during the prodromal stage.

Multiple sclerosis of the cerebellar type may show the classical picture of a paralysis agitans but this disease usually occurs in younger individuals, the cardinal symptoms being volitional tremors, which appear and increase with the effort to perform voluntary acts, nystagmus, which is generally lateral, scanning speech, and lastly, changes in gait occasionally combined with ataxia.

Postencephalitic Parkinsonianlike syndromes have been frequently observed in countries where encephalitis is epidemic. The striking feature of this encephalitis is the rather acute development and which is sometimes represented by the excitomotor type of Pierre-Marie and Gabrielle Levy.

Hysteria is sometimes mistaken for this disease, but here the occasional hypertonus is different, as is the tremor, the latter being more readily influenced by diversion and distraction.

Paresis, especially in cases involving the basal ganglia: Here the tremor is fine and is absent when the parts are at rest. The hypertonus is more or less evident, the pupillary reactions are involved and the serological findings easily aid in differentiating the two.

Senile tremor is not unlike the tremor in paralysis agitans, but its onset occurs much later in life, moreover, it begins bilaterally especially in the head, jaws and lips, and is unaccompanied by the characteristic rigidity of Parkinson's disease.

Posthemiplegic tremor is accompanied by a history of hemiplegia; there is paralysis and exaggerated reflexes and the disease is unilateral.

Retrocollic spasm.—Here only the neck muscles and frontalis are involved and the other symptoms typical of paralysis agitans are entirely absent.

Catatonic dementia precox.—This disease may be confused with paralysis agitans in young individuals, but the mental picture of schizophrenia is so characteristic that the diagnosis is seldom difficult.

Morbid anatomy.—No constant changes in the nervous system were found until recently. There have been many opinions: some believe it represents a presenile or senile degeneration involving the cerebellum, thalamus, or lenticular nucleus. The most pronounced lesions are, however, found in the mesencephalon. Brissaud was the first to point out the possible importance of a lesion in the substantia nigra as a cause of this disease.

Wilson (10) suggests changes in the corpus striatum, from certain resemblances to progressive lenticular degeneration. Hunt (11) localizes the motor part of the syndrome to disease of the motor cells in the globus pallidus, the vasomotor, secretory and trophic disorders representing central vegetative changes.

Vogt (12), Lhermitte (13), and others have demonstrated the reduction in the number of motor cells in the globus pallidus with accompanying neuroglia cell overgrowth in cases of idiopathic paralysis agitans. Lewy (14) in a series of fifty cases of idiopathic paralysis agitans, all of which showed a lesion in the globus pallidus, found alterations in the substantia nigra in eleven cases. Foix reports in cases of idiopathic paralysis agitans, pathological changes which were most prominent in the locus niger and globus pallidus, slightly predominating in the former location. Trétiakoff (15) believes that a lesion of the substantia nigra is responsible for paralysis agitans, basing his views on the examination of nine cases in all of which he found changes in the substantia nigra.

Lhermitte, Kraus and McAlpine placed little importance in the findings of Trétiakoff as he makes no reference to examination of the globus pallidus. The former believe that the changes found in the substantia nigra are secondary to the diminution and alteration in the cells of the globus pallidus.

In the majority of cases of idiopathic paralysis agitans there have been demonstrated definite lesions

in the basal ganglia, especially in the globus pallidus, corpus Luysii and substantia nigra.

In a later paper Lhermitte, Kraus and McAlpine (16) report the occurrence of abnormal deposits of iron in the brain of a case of Parkinsonism which exhibited no tremor. The abnormal deposits of the so-called "siderophilic substance" was found in each globus pallidus, in the form of globules; this substance was also discovered in the vessel walls. The deposit was mainly in the globular form and the vessels were much less affected. This distribution is unusual and differs from that found occasionally in paralysis agitans and other conditions in which the deposit is chiefly in the vessel walls. These findings they claim resemble those in some cases of epidemic encephalitis. They further state that they have as yet no proof that these deposits play any part in the symptomatology of paralysis agitans as similar deposits have been reported in other conditions.

(*To be continued*)

Epithelioma of the Lip Treated by Radiation

A. W. JACOBS, M.D.
New York, N. Y.

There is no longer any question as to the value of radium, either alone or in combination with some other therapeutic procedure, in the treatment of epithelioma of the lip. The case reported shows what can be accomplished by the proper use of bare tubes of radium emanation, so that the neoplastic tissue is destroyed without much loss of normal tissue.

CASE.—M. M., male, Italian, aged seventy-two, was referred to me on July 15, 1925, with the following history: About ten months ago a small blister, the size of the head of a pin, appeared on the lower lip, in the median portion, which continued to grow in size, and bleed when irritated. The patient's appetite was good, and there were no constitutional disturbances. He had been been smoking a pipe for many years, and was in the habit of using alcoholic beverages in a moderate amount. An operation was advised but the patient refused and he was then referred to me for therapy.

Physical examination showed a well nourished, plethoric adult male in good general condition. Teeth were in poor condition. The local lesion, in the median portion of the lower lip, was an elevated papillary and nodular oval shaped mass, with irregularly hard margins, about three by two by one cm., vascular, and covered with some grayish exudate. In the patient's neck a small soft gland was palpable.

On July 18, 1925, the treatment consisted of the insertion of bare tubes of radium emanation into the local lesion on the lip, followed by deep röntgen therapy to both sides of the neck. A total of twenty-one seeds of emanation, each containing 0.35 mc. making a total of 7.1 mc., were inserted into the lesion, followed by a full erythema dose of deep x ray to each side of the neck in half doses, within the following ten days.

Two weeks after the initial radium treatment, the lesion showed distinct evidence of shrinkage, necrosis and distinct improvement. Examination on September 18, 1925, about two months after the first treatment, showed an ulceration with hard edges and granulation tissue, with almost entire absence of neoplastic tissue. About six weeks later the series of röntgen treatment to the neck was repeated.

On November 3, 1925, a radium treatment (200 mg. hrs.) was applied to the lip for four hours. Examination on December 11, 1925, showed lesion of lip entirely healed and no evidence of neoplasia.

The patient is still under observation, and will receive further local application, when advisable. In this case a good result has been obtained so far, with practically no destruction of more of the lip tissue than the area involved in the growth.

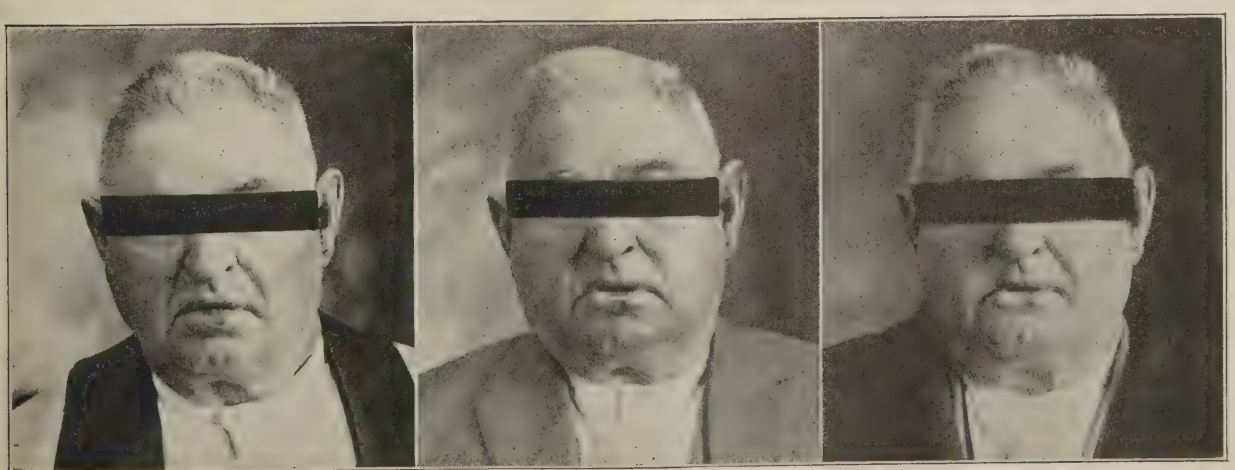

FIG. 1.—Case M. M., before treatment.

FIG. 2.—Same case as in Fig. 1, ten weeks after treatment.

FIG. 3.—Same case twenty-two weeks after treatment.

The Cystoscope as an Aid to Diagnosis*

JOSEPH SCHWARTZ, M.D.
New York

(*Concluded from page* 738)

Case X.—B. G., female, aged forty, complained of vague and indefinite pain in the right upper quadrant with no radiation and no relation to meals. She was thought by the family physician to have chronic cholecystitis. No cystoscopy was done. At operation a normal gallbladder was found and in search for other lesions to account for the pain a prolapsed freely movable right kidney was discovered which was undoubtedly responsible for her complaint.

In gynecological surgery the cystoscope should serve as a very useful adjunct in determining the effect of pathological conditions such as fibroids, cysts and malignant growths on the urinary organs. I have seen a specimen of a kidney which was removed under the guise of a fibroid tumor. Darner reports two ectopic kidneys which were interpreted as tuboovarian abscesses. Similar cases are reported in the literature. A study of the course of the ureters will sometimes avoid their injury during the removal of large tumors or in a difficult hysterectomy. If necessary, ureteral catheters should be left *in situ* as guides. In one of the cases where hysterectomy was performed the right ureter was injured and subsequently formed a ureterovaginal fistula. An attempt to repair proved unsuccessful and later necessitated the removal of the kidney.

Cervical cancers sometimes infiltrate the vagina and uterus and invade the bladder which becomes fixed to the uterus. In advanced cases periureteral infiltration may occur narrowing the lumen of the ureter and eventually causing back pressure on the kidney resulting in considerable damage to them. It is extremely desirable to ascertain the extent of involvement of the bladder and ureters, as in advanced cases the urinary organs may be so involved as to preclude any radical intervention.

Cystocele not infrequently gives rise to urinary symptoms such as dysuria, frequency of urination, etc.; other lesions must be excluded before such symptoms are attributed simply to such anatomical defect. One patient was admitted to the hospital complaining of frequency of urination and dysuria; there was a marked cystocele but on routine cystoscopy we discovered multiple papillomatous growths at the neck of the bladder.

Another elderly woman was sent to the hospital suffering from lobar pneumonia, when in the course of her convalescence marked vesical tenesmus and dysuria developed of which she complained bitterly. The urine was negative except for a slight trace of albumin. A marked cystocele was present. Cystoscopy revealed the condition of trigonitis areata alba as described by Pelouze.

Cystoscopy in children is a phase which has not been given as much attention as it deserves, perhaps because of the greater difficulty in accomplishing such investigation or because indications are deemed insufficient. It is believed by many urologists that the indication exists more often than the procedure is carried out. In a series of 4,905 autopsies in children Bugbee and Wollstein (1) found in 2.3 per cent. anomalies of the genitourinary tract. Infections superimposed upon such anomalies very frequently give rise to symptoms and are diagnosticated with precision only with the aid of complete cystoscopic examination. Many unexplained cases of pyelitis recurring or protracted are often the result of some malformation of the urinary tract. Obscure abdominal pain in children is too often regarded as of intestinal origin where in reality some lesion in the urinary organs may exist to account for it.

Illustrating the advantage of cystoscopy in children the following case is cited:

Case XI.—L. F., male, aged eight months, entered the hospital in a uremic condition. On examination there was found a markedly distended bladder. The urine contained pus. At the age of six months the child was operated upon for intussusception because of a mass in the lower abdomen. It is believed by some who saw the child that this mass was a distended bladder, as no classical symptoms of intersusception were present. After complete investigation of the urinary tract it was discovered that there were multiple diverticula of the bladder which were resected and the ureter reimplanted by A. Hyman. A subsequent nephrectomy followed because of a badly damaged right kidney due to a chronic infection.

In two children aged two and six years we found at autopsy in the former a congenital stricture of the left ureter with a hydronephrotic atrophy of the left kidney and in the latter a double pelvis and ureter of the right kidney. Neither had symptoms which were interpreted as necessitating cystoscopy.

CONCLUSIONS

1. The cystoscope should always be employed where symptoms referable to the genitourinary tract are present, even if the diagnosis has been established clinically. More than one lesion may be present.

2. In doubtful cases of chronic appendicitis or gallbladder disease or any other obscure abdominal condition the cystoscope should be used as a diagnostic measure in order that the urinary tract may be excluded as the offender.

3. In pathological conditions of the pelvis one should study the effect on the urinary organs.

4. In children where a diagnosis of an abdominal lesion is open to question, especially where the urinary organs may be the seat of the trouble, the latter should be investigated by means of cystoscopy.

Practical Therapeutics

X Rays in the Treatment of Diseases of the Skin and Other Pathological Conditions*

SAMUEL FELDMAN, M.D.
New York

The object of this paper is not a purely theoretical consideration of the physics and biology of the x rays. This has been discussed by me at length in another papers (1). What is intended here is a clinical study of the results of treatment with the x rays of a number of patients from my private practice.

In the treatment of skin diseases, there is not a single therapeutic agent as valuable as the x rays. One must, however, keep in mind that the rays are not a cureall and that in treating a skin affliction as well as an internal disease, the general condition of the patient must not be overlooked. The rays are used for their local effect only and even here they have their limitations. From these considerations, it would appear that the rays are valuable in the hands of a thoroughly trained clinician only. Knowledge of the x rays without a thorough understanding of the patient and the disease he is suffering from may prove very annoying to both patient and physician.

The rays are produced by the bombardment of electrons against the metal of the anticathode. This is brought about by the passage of a high voltage electric current through the tube. The higher the voltage the more rapidly will the electrons travel and the more forcible will be the bombardment. Upon this rate of travel of the electrons depends the power of penetration of the rays. High voltage produces hard rays which are highly penetrating, while low voltage produces soft rays. The latter do not penetrate deeply but are absorbed in the uppermost layers. For that reason, in superficial therapy, when the skin itself is being treated, this is sufficient. When we desire to treat an organ which is situated at some distance underneath the surface, we must avail ourselves of highly penetrating rays furnished by a powerful high voltage apparatus. In addition we also utilize several physical principles which tend to increase the penetrating power of the rays.

With proper doses, there is little risk of injury to the skin or internal organs. When a full dose is applied to the skin, a mild redness will appear in about ten days and wear off within three weeks. The quantity required to produce this is called the skin erythema dose. In treating skin diseases, different quantities are used at different times and these are measured against the erythema dose. In deep therapy, the dose is likewise expressed in percentage of the skin unit.

In treating diseases with the x rays, advantage is taken of the fact that different cells have different susceptibility to the rays. The younger and less differentiated cells respond more readily to their action than the older and more differentiated ones. For that reason it is possible, with the same dose to cause destruction of one group of cells and, at the same time, to stimulate others to increased growth. A good example of this is tuberculosis. While the tuberculous tissue is destroyed with less than fifty per cent. of the skin dose, fibrosis takes place simultaneously with the destructive process. In tuberculous conditions of the skin, glands, bones, and joints, the x rays have proved to be an agent of extreme importance. The general constitutional treatment of these cases, namely food, air, etc., must not be neglected. The x ray should also be supplemented with exposures to ultraviolet light for its direct germicidal effect, its general tonic properties, and its favorable influence on the calcium metabolism. Twenty-one cases of tuberculosis, among them scrofuloderma, tuberculous adenitis, orchitis, and several tuberculides were treated with uniformly good results. One group of cases of tuberculous adenitis deserves special mention, namely, adenitis of the tracheobronchial lymph nodes. These patients make the rounds, often for many years, with their dry hacking cough and pass as cases of bronchitis, hypertrophied tonsils, and what not, until someone, alert enough, has the chest x rayed and the true nature of the condition is found. The cough clears up and the patient improves in general health after comparatively few treatments. Five cases were treated with complete success.

ECZEMA AND ACNE

Among dermatological conditions which lend themselves to treatment with x rays, chronic eczema and acne furnish by far the greater number of cases. Of the latter disease, sixty-six cases were treated with sixty apparent cures, four improvements, and one nonimproved case. In five cases there was a mild recurrence, but they cleared up rapidly after further treatment. The essential feature of acne is the comedone formation. These become secondarily infected and the pustule is formed. The underlying mechanism of the pathology of this disease appears to be puberty, and time the only curative agent. The object of treatment of acne is to stop further comedone formation. This is best done with the x rays. Its action is twofold, by stopping the hyperplasia of the follicle and by diminishing the activity of the sebaceous gland.

There are many other skin diseases in which x rays are administered empirically or, at any rate, for their local effect only. In spite of the fact that in recent years much has been accomplished in ascertaining the etiology of skin diseases, the process in each individual case is tedious and often confusing. The patient is more interested in obtaining relief from his

*Read at a meeting of the North Bronx Medical Society, December, 1925.

suffering than in the permanency of his cure. This is true of all itching dermatoses including the various dermatitides and eczema.

One hundred and twenty-nine selected cases of chronic eczema were treated. The dry and infiltrated forms yielded the best results, while the moist types did not lend themselves as readily to this form of treatment. Very often it was necessary to treat these cases by other means until exudation was reduced to a minimum, when x ray treatment became possible. Extremely good results were obtained in the tylotic and crusted forms of the disease. One hundred and eighteen patients were apparently cured. Several resisted all efforts, while the balance were improved. The action of the rays in eczema is purely local and is brought about by the affinity of the rays for abnormal cells in the inflamed skin. As this does not in any way eliminate the cause, recurrences are to be expected in a certain number of cases with obscure etiology. There were nine recurrences in this group. In all of these patients, however, the condition cleared up after further treatment.

Twenty-seven cases of seborrheal dermatitis cleared up rapidly under this form of treatment. There were only two recurrences.

There is a group of generalized scaling eruptions which has hitherto resisted all efforts of the dermatologist. They all cleared up after a course of x ray treatments. This group included two cases of universal lichen rubra pilaris and two of dermatitis exfoliativa, one following psoriasis and the other of unknown origin.

The comparatively recent discovery of the epidermophyton resulted in the splitting off of a large group of dermatoses from the general group of eczema and is known as eczematoid ringworm. Together with eczema marginatum, intertrigo of the webbs of the fingers and toes, and a large number of cases of dyshidrosis, it constitutes a large portion of the average dermatologist's practice. They are all presumably due to epidermophyton infection, although that organism can not be demonstrated in every instance. Whitfield ointment and potassium permanganate are beneficial. Yet, for quick relief and even cure, there is nothing to compare with the x rays. Fifty-eight cases were treated with fifty-three apparent cures and five improvements. There were three recurrences in this group. The less favorable results were obtained among patients with the dyshydrotic form of the disease. The reason for it may be that x rays do not destroy germs. The ultimate cure of infectious skin diseases by the rays depends upon the tissues ridding themselves of the invaders by a process of exfoliation. Bacteria and fungi are thrown off in the scales. In superficial infections, this is quite easily accomplished. The same is not true of dyshydrosis in which the infection is deep seated and involves the epithelium as well as the sweat gland ducts.

Eczema occurring about the anus and genital region is a very troublesome condition. It is most commonly caused by local irritation due to discharges from the rectum or vagina, chronic hemorrhoids, and local epidermophytosis. A number of these cases are due to scratching in diabetic pruritus. Where the cause is found and eliminated, x rays yield almost perfect results. In cases with obscure etiology, recurrences are frequent. Even then, great benefit results in giving the patient relief, though it may be for a short time only. Twelve chronic cases were treated with but few recurrences. In the acute form of the disease, there is occasionally an aggravation of the itching and irritation after the first x ray exposure. This is only temporary and of no serious consequences, yet the patient is likely to be intolerant and discontinue the treatment before actual results can be obtained. These cases require ingenuity in management, not only of the disease, but also of the patient.

PSORIASIS

With the advent of endocrinology, some evidence of a relation between disturbances of the thymus and psoriasis has been found. This led, in this country, to the treatment of that disease with thymic extract and abroad, with a stimulating dose of x rays applied to the thymus. I have tried both methods in a number of cases, but am unable to express an opinion as to their efficacy. Improvement, if any, was very slow and it became necessary in all cases to resort to the application of x rays directly to the lesions. In spite of the fact that one can not speak of a cure in psoriasis, this method of treatment is much superior to ointments. It is clean, hence more convenient to the patient and results are obtained more rapidly. Thirty-two patients had their lesions removed by this method. There were eight known recurrences. In one case, the treatment had to be discontinued. This was a universal case and for the purpose of treatment, the body was divided in sections and treated one part at a time. The first portion yielded to three x ray applications. The recurrence here was so rapid, that during the treatment of the second section, a new crop appeared in the cleared up region. Further treatment was deemed inadvisable. Psoriasis patches appear to develop a resistance to the action of the rays after treatment. When a patch recurs after x ray treatment, it will not respond as readily to further treatment as it did in the first instance. On the other hand, it has been observed that treated patches are more apt to yield to medication, ammoniated mercury, for example, than patches that had no x rays applied to them. Occasionally a case is encountered which does not respond to x ray treatment from the outset.

SYCOSIS

The disease known as sycosis is amenable to treatment by means of temporary but total epilation of the hair by radiation. Ringworm and favus are treated in the same manner. The technic requires four fifths of an erythema dose of x rays, filtered through one millimetre of aluminum, and applied uniformly over the entire surface. The hair falls out about eighteen days after the application. The fungi and bacteria are thrown off with the hair. The latter regrow in from six weeks to three months. This work requires extreme care as permanent alopecia may be the result of imperfect technic. If isolated hairs remain after the x ray epilation, they must be removed by means of an epilating forceps, or else the disease may recur. In staphylococcus sycosis, especially, there is always some tendency to recurrence and the treatment may have to be repeated

after the new crop of hair reappears. Eight cases of sycosis, five of ringworm, and one of favus were successfully treated by this method. In one case of sycosis the condition recurred and there was need for further treatment.

Permanent epilation by means of radiation for the cure of hypertrichosis must be condemned because of the serious sequelæ that frequently follow.

Diseases of the nails such as eczema, psoriasis, and ringworm, which do not respond to the old method of treatment, yield quite satisfactory results with the x rays. A total of eight cases in this group were treated by this method with good results.

BLEPHARITIS

Blepharitis is another condition in which the results obtained from radiation therapy far surpasses all other methods. This treatment has become possible because of the knowledge that the eye structures offer a greater resistance to the destructive power of the rays than does the skin. Six cases of marginal and one of ulcerative blepharitis were successfully treated. In treating blepharitis, the rays are applied to the open eye and, naturally, the lashes remain unshielded. Four weekly applications are given, each one consisting of one quarter of an erythema dose, making it a total of one full erythema dose within a period of one month. There is no evidence of loosening or falling of the lashes, in spite of the fact that the hair will fall after four fifths of an erythema dose, if applied in one sitting. This demonstrates the extent to which the tissues may recuperate in vitality and function within that period of time.

Lichen planus, the neurodermatides, and all chronic itching dermatoses are favorably influenced by the rays.

PRECANCEROUS DERMATOSES

In the precancerous dermatoses, such as Paget's disease, dyskeratosis of Bowen, the seborrheal wart, and the premycotic stage of mycosis fungoides, the use of the x ray is of inestimable value. With the possible exception of the last one mentioned, the x rays will in all probability cure the condition and prevent malignancy in all cases. A number of cases of seborrheal keratosis were treated with complete disappearance of the lesions.

EPITHELIOMA

The treatment of rodent ulcer or basal cell epithelioma occupies a position midway between superficial and deep therapy, while the tumor itself forms the borderline between the benign and the malignant tumor. As all benign tumors except fibromyoma of the uterus, respond poorly to radiation therapy, this epithelioma is also slow in its response to that method of treatment. Sixteen cases in all were treated. Originally, the method consisted of deep radiations only. There was healing in every case, but recurrences were frequent and it became necessary to remove the growth by means of surgical coagulation. The process is now reversed. The tumor is removed and, after the wound is healed, x rays are applied as a prophylactic measure. The results are uniformly good.

Even in prickle cell epithelioma, as well as in all accessible malignancies, provided they are still operable, surgical intervention, preceded and followed by radiation therapy, appears to yield the most promising results. Surgical diathermy or the socalled endothermy does not open up the vascular channels and, in this manner, reduces the chances for metastasis to a minimum. The technic outlined above is not applicable in cases of lymphosarcoma and, to a lesser extent, in round and spindle cell sarcoma. There is nothing to be gained from surgery, because tumors of this class, especially the lymphosarcoma, yield so rapidly to x ray treatment that a complete disappearance of the growth sometimes takes place within a few days after treatment. Bone sarcoma, also fibrosarcoma, myxosarcoma, and chondrosarcoma are not much benefited by radiation therapy. Six cases of lymphosarcoma were treated. In one of the older patients mediastinal metastasis developed. Of the remaining, three had no recurrence six, seven, and eleven months after treatment.

In estimating the results of treating lymphosarcoma, one must not forget the possibility of error in diagnosis. Biopsy is a dangerous procedure. It predisposes the patient to metastasis formation. The diagnosis is made by physical examination and by the socalled therapeutic test, namely, the rapid disappearance of the tumor after radiation. Both may be misleading. The rapid disappearance of the tumor after radiation does not mean that we have a sure cure for this form of malignancy. Recurrence and metastasis are frequent.

OTHER MALIGNANT GROWTHS

Of the other malignant growths in which radiotherapy is of any use, breast cancer, malignant tumors of the uterine fundus, and, to a lesser extent, those of the cervix, promise the best results. Eleven breast cancers were treated, seven of them after amputation and four were inoperable cases. In two of the latter cases the patients died of metastasis, while the remaining two are alive and considerably improved six and ten months after beginning of treatment with the combined method of deep radiation and implantation of radium emanation seeds. In the seven postoperative cases, two patients reported for treatment after skin and mediastinal metastasis had developed and died a short time after. The five remaining are apparently well to day, after periods ranging from one to three years respectively. One patient with cancer of the uterine cervix is alive three years after the first course of treatment with radium and x rays. This patient does not show any signs of recurrence or metastasis. In a case of carcinoma of the lung the patient is improved both in the local condition of the tumor and in general health two years after a course of x ray treatment was instituted. The results obtained from radiation treatment in cancer of the liver, stomach, and esophagus did not justify the efforts. Hypernephroma yields quite readily to x ray treatment, yet the outcome is rapidly fatal. A patient with a large mass in the abdomen, resembling splenomegaly, was treated. There were no urinary symptoms. The mass disappeared almost completely after radiation. Four months later there was a recurrence. At this time, seven months from the first treatment, there is evi-

dence of cachexia and possibly metastasis. Five postoperative cases of rectum carcinoma were treated with x rays and radium. These patients are all alive and apparently well. The period of well being is, however, too short for statistical purposes, the longest being two years. Six cases of lymphogranuloma or Hodgkin's disease were treated. All patients showed improvement at first, but the disease recurred in every case. These patients do not respond as well to a repetition of the treatment and, finally, the rays seem to have no effect upon the tumor.

FIBROMYOMA OF UTERUS

Turning again to the brighter side of radiotherapy, the treatment of fibromyoma of the uterus looms up in the limelight. Barring a group of cases that are more suitable for surgical intervention, as, for example, myomata in young women where there is a possibility of myomectomy with a chance of pregnancy, and cases complicated by suppuration, liquefaction, inflammation of the adnexa, and suspicion of malignancy, the remaining sixty-five per cent. of all cases yield practically perfect results. The same is true of preclimacteric bleeding in which the cause can not be ascertained. Twenty-one cases of fibromyoma of the uterus were treated. In fifteen, amenorrhea resulted after a single course of treatment, in three cases after two courses, and in the remaining, a third course was required before the bleeding stopped completely. In five cases of preclimacteric bleeding, amenorrhea resulted after one course of radiation treatment.

PROSTATIC HYPERTROPHY

Another disease in which radiotherapy should receive first attention is prostatic hypertrophy. Four patients with that disease were treated. They ranged in age between sixty-seven and seventy-eight years. Three of them already led a catheter life and in one the frequency of urination amounted to once every half hour. They were all cured of their symptoms. One received three courses of treatment, two had two courses each, and one, a single course only. The technic is similar to the one used in uterine myoma. Occasionally a swelling of the organ takes place several days after the treatment. This is true of all glandular organs, but in the case of the prostate it may lead to very distressing symptoms, such as tenesmus, frequency of urination, etc. To avoid this, it is better to proceed rather slowly with the treatment so as to give the tissues a chance to recuperate before each successive field is rayed. Comparing the absence of danger and the comparatively small inconvenience to the patient treated by this method with the mortality from surgery, there can be only one opinion as to the method of choice.

One case of enlargement of the prostate, in a young man twenty-four years old, responded to the same method of treatment. The enlargement was presumably due to an old gonorrheal infection.

HYPERTROPHY OF THYMUS

Hypertrophy of the thymus with its troublesome and, at times, threatening symptom complex can be cleaned up with about six exposures to the rays. Eleven children were treated. In six, the treatment was completely successful, while the others dropped out before the course of treatment was completed, some of them after considerable improvement.

HYPERTHYROIDISM

Good results can be obtained in a certain number of cases of hyperthyroidism. I can only report two apparent cures, but considering the fact that these were the only two patients who finished their course of treatment, the results can not be regarded as bad. There were five other cases. In two of them the treatment was discontinued after the first or second session on account of increased toxicosis. They were very bad cases from the start. The others dropped out of their own accord.

CONCLUSION

In conclusion, mention must be made of the use of the rays in some constitutional diseases. Improvement, though temporary, is obtained in the leucemias by raying the spleen, glands, and cancellous bone. Raying of the spleen has proved to be efficacious in checking hemorrhage from any origin. It has given excellent results in the treatment of the various forms of purpura.

Are Bacteria Killed by the Usual Staining Technic?—Adam Schmidt (*Klinische Wochenschrift*, September 3, 1925) has been enabled to show that bacteria are not killed by the usual heat fixation and subsequent staining with alcoholic watery solutions of aniline dyes, and that even with carbol fuchsin staining, the mere resistant bacteria retain their viability. Only with the gram stain are bacteria regularly destroyed. Consequently the following directions must be carefully observed because of the danger of infection: 1. The slides must be heated sufficiently. 2. The wash water must not be drained into the sink, as is usually done, but must be poured into a special receptacle and there disinfected. 3. Filter paper should not be handled carelessly but must be made innocuous after its use. 4. After their examination, the specimens must immediately be placed in a disinfecting solution.

A New Technic in the Application of Thiersch Skin Grafts.—Daniel McLellan (*Canadian Medical Association Journal*, September, 1925) lays on a sterile towel a strip of zinc oxide adhesive plaster, one inch wide and long enough to go completely across and adhere firmly to the skin on both sides of the raw area, with the adhesive side up. Six or eight thicknesses of gauze, one inch wide and long enough to go across the wound, are laid along the middle of the plaster strip, and a thin layer of vaseline applied to the surface. The Thiersch graft is cut in the usual way and laid, raw side up, on the vaselined surface of the gauze, the edges straightened out with a probe. Taking the adhesive by both ends the graft is applied, the adhesive being stuck firmly to the good skin on each side. This was left in position for eight days, when the adhesive was cut at the junction of the raw surface and the good skin, and turned back carefully.

The Influence of Cervical Sympathectomy on Angina Pectoris*

HOWARD LILIENTHAL, M.D.

New York

I shall not review here the history of angina and its attempted relief with its hundreds of clinical and experimental reports, but I shall give you my own impressions gathered from many sources and from my own experience.[1]

First, as to diagnosis—from its very name, angina, we assume the presence of great pain. This usually appears in paroxysms of variable duration, but, in addition to the pain with its well known radiations, there are other symptoms which are so multitudinous that it is difficult to classify them. It seems also that the anginoid attacks are not always due to the same pathological condition. Wenckebach has gone so far as to divide angina into two distinct forms—one that he calls the chronic type in which there are repeated attacks, often of the greatest severity but with apparent health between and without objective signs; and the other, which he calls acute, in which the first attack leaves the patient broken and ill for a long time and which is never followed by a complete recovery with apparently normal cardiac conditions.

After reviewing the various descriptions of both classes I conclude that the socalled chronic type of the disease probably originates in the aorta (Allbutt) and is due to pure spasm with tension of the vessel wall. This may well be compared to the pain known as colic in other hollow viscera, and *vascular colic* would not be a bad descriptive designation of this phenomenon. When the spasm has passed, the patient feels perfectly well, much as in biliary, uterine or renal colic, relief coming when the visceral tension has gone.

In Wenckebach's acute form there are added to the colicky condition signs that point to the coronary arteries as the place of origin of the pain whether it is purely spasmodic in character or accompanied by disturbances in the vessel wall or lumen such as thrombosis or embolism. One can easily understand how a sudden interference with the blood supply of the cardiac muscle must also produce instant and grave changes in the action of the heart often ending fatally in a few moments. Occasionally there are slower changes associated with permanent cardiac disturbance which may last for a much longer time. Indeed, the effect of a slowly progressive blocking of even an important coronary branch may be partly nullified by the collateral blood supply through anastomotic vessels. Doubtless the two causes of angina may be coincident, i. e., the aorta and the coronaries may participate in the picture. In the aortic form of the disease (aortalgia) there is usually no change in either the sounds of the heart or in the rate and tension of the pulse no matter how agonizing the pain may be, while in the coronary type, whether due to spasm (which has never yet been experimentally demonstrated) or to mechanical occlusion, there will necessarily be a reduction in the power and regularity of the heart beat easily demonstrable in the peripheral arteries and often accompanied by the usual signs of cardiac failure such as edema of the lungs.

It is hardly necessary for a mere surgeon to discuss in detail the physiology involved. Indeed, cardiology has become a special branch of medicine and while it is the surgeon's responsibility to assure himself of the ability of the patient to endure operative therapy, he must depend upon his medical colleague for the finer points of diagnosis. Nevertheless, it is essential that the surgeon should be able to recognize in a general way that his patient is really suffering from a serious cardiac condition.

The pain of what I call the aortic form of angina is excited by anything which increases the blood pressure or the cardiac blood volume (Wenckebach); exertion, cold, excitement after a full meal, etc. Immediate rest is imperative and instinctive and tends to quiet the attack. Objective examination, as I have suggested, will disclose nothing pathognomonic. The surgeon must clearly understand that during any attack of angina there is the threat and possibility of death, in some instances due to the pain itself. In the acute or coronary form there may be slight sensations to warn the patient, or the attack may be absolutely sudden, appearing at any time, even during sleep. Danielopolu divides the syndrome into two kinds, *Angina d'effort* and *angina de decubitus,* and

*Read before the Medical Association of the Greater City of New York, November 16, 1925.

[1]An important symposium on angina pectoris is now about a year old. It was held before the Vienna Society for Internal Medicine and Pediatrics. The principal speakers were Wenckebach of Vienna, Tschermak of Prague, Danielopolu of Bucharest and Eppinger and Hofer of Vienna.

holds that only the former should be selected for operation. Still, we have already seen that the nerve tracts carrying the pain from aorta or coronaries are identical and his reasoning, which leads him to think that effort stretches a diseased aorta and produces the pain, would also lead to the conclusion that spasm or tension within the coronaries may yield to the same remedy.

It is recognized that certain groups of angina may occur without pain and the condition has been described as *angina sine dolore,* or painless angina. These cases certainly would hardly be suitable for operative treatment.

Although postmortem examination usually shows some sign of coronary disease, it has never been clearly demonstrated that angina pectoris is necessarily caused by these lesions and it is well known that coronary disease without angina is very common. Allbutt states, however, that in every case of angina there is disease of the ascending aorta; but, as before stated, both the aorta and the coronary have the same innervation for the production of the same kind of pain.

It has been suggested that habitual hypertension is one of the causes of angina, but individuals with normal blood pressure may also suffer.

Wenckebach believes that some form of nerve resection will probably cure or relieve the pain though manifestly it cannot eradicate the disease. The suggestion of nerve resection was made many years ago by Francois Frank. In 1916 Jonnesco operated with some success by resecting the entire sympathetic chain of one or both sides of the neck.

SURGERY

From this very elementary sketch, the problem of the relief of the painful phenomena of this disease or complex divides itself into two distinct parts; first, that of merely interrupting the tract which carries the sensation of pain to the brain; and second, reducing or abolishing the vascular spasm which produces the agony.

The first of these suggestions would seem simple enough were it not for the fact that recent empirical work on human beings has upset many of the opinions of the physiologists and there is no unanimity of opinion as to the exact direction of the sensory path to the brain. The second would also appear simple were it not that it is only by what may be called clinical experiment that facts have been discovered which it will be the business of the physiologists to explain.

We will discuss briefly the first of these questions, namely, whether it is desirable to rest content with a mere nerve blocking operation and, if so, how this can be most easily, safely and thoroughly accomplished.

Goodall and Earle in 1913 suggested division of the second, third and fourth thoracic sensitive nerve roots and since then there have been experiments by injecting these nerves with anesthetics (novocaine) in order to block them.

I have been told by George I. Swetlow that he has had success by injecting the posterior nerve roots with alcohol without a cutting operation. One of his half dozen patients remained well after six months. Swetlow has not observed any untoward symptoms following his procedure.

Other suggestions are the division of the depressor nerve which was first carried out by Eppinger and Hofer. They reasoned that because there is evidence that this nerve is sensory from the aorta, its division would be followed by relief; but, unfortunately, the depressor nerve in human beings is not easily found on dissection and may be missed altogether. It is almost certainly a part of the vagus and a dissection of this important trunk would be necessary in order to identify the depressor strand. To me this appears a formidable procedure when carried out upon the cervical part of the nerve.

In herbivorous animals the depressor nerve is well developed and easily found. Eppinger and Hofer even went so far as actually to divide the vagus in the neck in order to make sure that the depressor nerve had also been severed. This patient died of pneumonia. One patient died of laryngeal paralysis from simultaneous bilateral division of the superior laryngeal nerves for which tracheotomy had to be done.

The physiology of the depressor nerve function appears to me to be somewhat confused. If after division the upper end is faradically stimulated there is a fall in blood pressure. Why the section and not the stimulation of this nerve leads to diminished pressure it is hard to understand. At any rate the idea of cutting this nerve was conceived because it probably carried sensory fibres from the aorta. Danielopolu also suggests division of the vertebral nerve which passes from the stellate ganglion to the cord.

We will now take up the second method of relief—that which tends to reduce the spastic tendency in arteries. Surgeons have long recognized from their work in local anesthesia upon the larger bloodvessels that dissecting the outer coats of these vessels or ligating the vessel itself is accompanied by pain. I have exposed and handled the thoracic aorta with production of pain. It has also been shown by Jaboulay and, more recently, by Leriche, that stripping the adventitia from large vessels, this coat containing the sympathetic plexus, is followed by vascular paralysis and dilatation for a considerable distance below.

Tuffier dissected the adventitia from an aneurysm of the aorta, in order to tape it with a strip of fascia. There was relief from the pain of aneurysm and Delorme took this to be due to the removal of the sympathetic plexus.

There is reason to believe that the division or, better, the extirpation of the cervical sympathetic might have a paralyzing effect upon the aorta and perhaps also on the coronaries so that vascular colic would be impossible. To this paralyzing effect we may, in part at least, ascribe the relief afforded by the nitrites. Levine says that these drugs do no good when there is disturbed cardiac function. The nitrite test appears to me to be a fair one in deciding as to the probability of relief by sympathectomy.

From my own cases I can say that extirpation of a part of the cervical chain invariably produces some easily demonstrable reduction in the blood pressure. But the reduction has been in four out of five cases only temporary. Still, relief from the attacks or the diminution in their number has been encouraging.

Now comes the important question as to how much is necessary or advisable in the procedure. Should

the entire chain with the upper thoracic ganglion be extirpated (Jonnesco) or is it sufficient to remove merely the superior cervical ganglion? (Coffey, Brown and Kerr.) This will have to be determined by further operations, each one of which in our present state of knowledge must be regarded as a clinical experiment. Coffey and Brown, also Kerr, are of the opinion that the extirpation of the upper ganglion will accomplish as much as the more radical procedure and with much less technical difficulty and consequent danger and my own best case would lead me to the same conclusion. But physiologists try to explain this by assuming that sensitive fibres traverse the ganglion; a fact unsuspected until now.

A complete report of my own cases will be published at a later period.

Case I.—I will say, here, however, that my first case, that of a man sixty-two years of age, with frequent attacks diagnosed as angina by Dr. S. A. Levine of Peter Bent Brigham Hospital, was practically living on nitroglycerine which gave considerable relief. There was no evidence of coronary disease but there was hypertension (systolic 180). It is now a year and nine months since I avulsed his left superior ganglion and dissected out the nerve including the middle ganglion. Relief had been complete so far as the painful symptoms were concerned and the patient led a normal active life. He still felt, however, that the disease was present although absolutely without pain. I consider that this is as nearly a cure as may be hoped for in angina pectoris. Immediately after his operation the blood pressure dropped to 113. It was 160 just before the anesthesia was given. There had been a gradual rise to about 150. [Note of June 6, 1926: I have recently learned that this patient after more than two years of complete relief is now suffering from symptoms of coronary thrombosis.]

My next three patients were women, two of them with hypertension up to the limit of my manometer which reads to 300. In all these cases there was an immediate though temporary drop in the blood pressure following each procedure. All were treated by sympathectomy including avulsion of as much as appeared safe of the lower ganglion. It was necessary to operate on both sides in all except the first case, for although there was relief for varying time following the first operations the symptoms recurred within from one week to three months with a return of the hypertension.

My last case was that of a man with various neuroses in addition to his anginoid attacks, including arteriosclerotic nerve deafness of the right ear. He expressed himself as not relieved. None of the patients suffered any alarming symptoms during the operation or the convalescence from these nine resections. From this experience and that of others, I believe that if a sympathetic nerve resection is to be performed, it would be just as likely to be followed by success if only the superior and middle ganglia were removed.

CONCLUSIONS

1. The symptom complex known as angina pectoris is probably caused by tension within the walls of the ascending aorta or of the coronaries or both.
2. If this tension is the result of obstructive changes within the coronary arteries, the chances for relief by operation are not as good as in the aortalgic type.
3. Relief by nitrites would appear to be a test of some value in deciding upon sympathectomy.
4. There are two types of operation upon the nerves, one the blocking of the pathway of pain to the brain, the other tending to prevent vascular spasm or colic which there is reason to believe may be influenced by avulsion of the superior sympathetic ganglion.
5. Other things being equal, the procedure involving the least danger should be tried first, even though it consists of the mere blocking of painful sensations. An example of this therapy would be the alcohol blocking of the upper thoracic sensitive branches without incision. (Although procedures which tend to prevent spasm are more likely to prolong life.)
6. The question of operation must be decided in each instance by the cardiologist, the surgeon and the patient.
7. Finally, in a case diagnosed as angina the frequency and severity of the pain and the resulting incapacity should be deciding factors.

Mitral Stenosis*

MARK GORDON, M.D.
Brooklyn, N. Y.

The subject of mitral stenosis, the severest of all cardiac lesions, has attracted interest for considerable time both from the clinical and experimental standpoint. Ever since Bouillaud formulated his laws of coincidence bearing upon acute rheumatic arthritis and endocarditis with Andral, Potain, Frederich and many others, proving clearly the infectious origin of this disease, clinicians have urged its early recognition. The early recognition of mitral stenosis, however, not infrequently presents difficulties even to skilled and experienced clinicians chiefly due to the absence of classical symptoms of the disease, which often do not make their appearance until damage to the heart muscle has proceeded to an alarming degree.

This lesion occurs twice as frequently in women as in men, occurs at all ages, but more frequently in young adults. It is due to some infection, more often rheumatic. Although a certain number of cases of mitral stenosis have no clinical relationship to rheumatic fever, yet these cases have uniformly shown the same pathology as those associated with a rheumatic history. For example, in Peking, China, mitral stenosis is the most prevalent valvular disease, although rheumatic fever is rarely seen. Other

*Read before the East New York Medical Society May 24, 1925.

etiological factors are diseased tonsils, grippe, exanthemata and pneumonia. Infection occurs often without memorable symptoms so that a long time may elapse between infection and cardiac involvement.

In considering the pathology of mitral stenosis, it should be remembered that in the normal heart the blood flows unobstructedly from the left auricle into the left ventricle and no audible sound is produced during its passage. When structural changes are present in the valves which thicken its cusps or form adhesions of the leaflets, a state of obstruction takes place. These changes throw an excessive burden on the right heart, which, in its endeavor to maintain the circulatory equilibrium, becomes hypertrophied. This is relatively more pronounced in the right ventricle. These changes have been found in many cases which have not given any symptoms of heart failure as proved by Cotton.

Physical signs of mitral stenosis are usually found long before any symptoms of cardiac failure appear. The apex beat may be seen in the midclavicular line, a thrill is felt over the apex and a diastolic shock may be felt over the base. Percussion elicits little enlargement to the left. Oftentimes, enlargement of the left auricle can be made out. There is, however, definite enlargement to the right of the sternum.

The murmur in mitral stenosis is set up by the flow of the blood from the left auricle into the left ventricle through a constricted mitral valve. The smaller the constriction the greater must be the velocity of the blood to produce the murmur. That is why some cases present the murmur only after exertion when the flow is stimulated. As the orifice becomes more constricted a lesser velocity of the blood is required to produce the murmur, and then it is heard all the time. The murmur is also heard with greater intensity in the recumbent position. These changes give a fair appreciation of the severity of the lesion.

The murmur is diastolic in time, low pitched and rumbling, and attains a crescendo character just before merging into systole, which is due to additional push given the current by the contracting auricle. The murmur is generally spoken of as presystolic. That the high pitch which the murmur attains is due to the contraction of the auricle is evidenced by its disappearance when the latter is in a refractory state, as in auricular fibrillation. The first sound may be accentuated or snapping as a result of futile contractions of the ventricle in the presence of insufficient blood. When the ventricle has enough blood there is a pushing element to the apex. In much advanced constriction of the valve a middiastolic murmur can be made out which is diminuendo in character giving place to the presystolic murmur. This murmur persists during auricular fibrillation when the auricle is paralyzed. Another murmur, diastolic in time, known as the Graham Steele murmur, is said to be heard over the second left interspace. It is produced in well advanced cases as a result of dilatation of the right auricle, conus arteriosus, and pulmonary ring.

Mitral stenosis gives rise to cardiac irregularities, such as auricular fibrillation, paroxysmal tachycardia and heart block as a result of tissue changes in the heart muscle.

The symptoms of cardiac failure in mitral stenosis are not as much a result of valvular changes as the inability of the heart muscle to maintain the circulatory equilibrium This is owing in part to disease of the heart muscle itself and to exhaustion of the heart on account of constriction of the mitral valve.

Even before actual symptoms of cardiac failure appear the patient becomes weak, anemic and undernourished because of insufficient blood supply to the body. The earliest symptoms are those of disturbed pulmonary circulation, characterized by dyspnea, cough and expectoration occasionally tinged with blood. Bronchitis is an early symptom and hemoptysis is not uncommon. Sometimes these signs are mistaken for pulmonary tuberculosis. Dullness in the upper left chest may be at times made out, due to large left auricle. As the disease advances still further there is dilatation of the right ventricle with relative tricuspid insufficiency and venous engorgement. This condition may lead to epistaxis, gastric and intestinal symptoms with pain over the liver due to enlargement of the organ. In extreme cases liver pulsations appear and the veins in the neck become prominent.

Hoarseness due to pressure upon the recurrent laryngeal nerve may occur. Ortner first described this condition in 1897; since then a number of cases have been reported by other investigators. I have not met with such complications in my cases. Thrombosis is not an infrequent complication, especially when there is auricular fibrillation. This frequently occurs in young persons and is often responsible for the occurrence of cerebral embolism. Secondary nephritis due to venous and embolic infarcts is frequent.

Statistical studies show that the average age of death from mitral stenosis is thirty-five years. Owing to associated diseases of the heart muscle, the prognosis is unfavorable. When the disease is progressive, complete compensation cannot be established.

In a series of twenty-three cases of mitral stenosis in my practice, tabulated during 1923 and 1924, I wish to emphasize some data bearing upon their history and etiology. There were seven males and sixteen females. The ages varied between twenty-one and forty-five.

Two cases gave a history of definite rheumatic infection. Three gave a history of scarlet fever and diphtheria. Five gave a history of diseased tonsils, grippe and pneumonia. Four gave no definite history of infection, but that of gastrointestinal disturbance.

It is interesting to note that in two cases the family history was that either father or mother or both had heart disease or died of it. Four cases gave a family history of either a brother or sister being affected by heart diseases.

For obvious reasons, not all cases can be presented in this paper. I have, therefore, selected three cases, which, to my mind, illustrate mitral stenosis in its mildest and severest forms.

Case I.—Mrs. S., twenty-two years old, married, one child, nine months old, came for treatment October 9, 1923. Mother died of heart disease when patient was young. She never had any serious illness. Does not remember childhood diseases. Had mild attack of influenza during epidemic. Since birth of baby she felt weak, was short of breath, and felt tired. The condition was affected by the weather.

Bowels were regular. The patient coughed occasionally.

On examination, patient appeared quite robust, high color in the face with signs of dyspnea. Tongue was clear. Lower teeth showed pyorrhea. The throat was congested and presented large, cryptic tonsils. The chest was well formed, of good expansion. Apex beat seen in the fifth interspace in midclavicular line. Palpation elicited a thrill over the apex. Percussion gave evidence of enlargement of cardiac area to the right. Auscultation elicited a presystolic murmur, of rumbling and crescendo character. The first sound was well accentuated, so was the second pulmonic. There was no evidence of any venous engorgement nor pulsation of vessels in the neck. Heart sounds regular, of good quality. Lungs presented evidence of mild bronchitis. Abdomen negative. No evidence of edema. Pulse 90-regular, good quality. Blood pressure 125-70. Urine negative. Hemoglobin seventy per cent. A diagnosis of mitral stenosis with relative mitral insufficiency was made. Fluoroscopic study confirmed findings.

Treatment consisted of removal of tonsils and correction of teeth, with instruction as to exercise and diet. She was under periodical observation until October 10, 1924. All dyspnea disappeared. The pulse ranged between 76-80. She attended to her ordinary housework without difficulty and was discharged October 10, 1924. Patient has since been seen and is in good health.

Case II.—Mrs. D., aged forty-seven, came under observation November 20, 1923. Does not remember childhood diseases. At age of twenty-five had attack of rheumatism from which she completely recovered. Married at thirty, gave birth to two children. First birth uneventful. After birth of second child was confined to bed a few months with heart trouble. Apparently recovered but remained weak.

On examination, patient appeared dyspneic. Face pale with dusky patches over cheek bones. Lips slightly cyanosed. Mucous membranes of mouth bluish. No teeth. Throat presented some dryness, otherwise negative. Chest of good expansion. Apex beat not seen. No pulsations were evident. Palpation elicited a faint thrill over the apex. Apex beat seen in the fifth interspace in about the midclavicular line. Percussion presented a moderate amount of cardiac enlargement to right especially. Auscultation elicited a rumbling murmur over the apex, crescendo in character, heard at the end of the diastole and heard more distinctly in the recumbent position. There was accentuation of the second aortic. Abdomen negative. Liver edge well defined on palpation. The lower extremities presented some varicosis, no edema. The pulse was 100-full and throbbing. Blood presure 180-90. Hemoglobin sixty per cent. Urine, specific gravity 1025. Goodly traces of albumin, no sugar. Occasional red cells, no pus.

Fluoroscopic examination of chest confirmed clinical findings. On the strength of her history, clinical findings and fluoroscopic study, I made a diagnosis of chronic valvular disease, characterized by mitral stenosis with a secondary nephritis.

After some rest in bed and exhibition of digitalis, patient felt better. The kidney condition improved and blood pressure came down. Attacks of paroxysmal tachycardia developed, however, which were readily relieved with quinidin. The pulse, however, did not come down lower than 100.

Case III.—Mrs. B., aged thirty-five years, married, two children. Had influenza three years ago. Came under observation December 6, 1923, complaining of shortness of breath, inability to do any kind of work, pain in upper right quadrant of abdomen, headaches, poor appetite, general weakness and insomnia. Bowels constipated. Lower extremities edematous. Impaired vision. Annoying cough.

On examination, patient cyanotic, dyspneic. Teeth poor. Tongue coated. Throat congested with evidence of one, large, apparently diseased tonsil. Neck negative. Apex beat seen in sixth interspace well to the left of midclavicular line. A pronounced thrill felt all over precordia with a shock over the base. Percussion presented a very large area of cardiac dullness both right and left. Auscultation elicited a loud, rumbling sound, heard over the entire precordia. Another murmur was heard within a circumscribed area over the apex, diastolic in time. Accentuation of the second pulmonic. The lungs presented râles all over, giving evidence of bronchitis. The abdomen was rather tense and very tender over the liver which was palpable about four finger breadths below costal arch. The spleen was palpable and tender. There was no evidence of edema or fluid. The lower extremities were edematous. The pulse was sixty, irregular, sluggish. Blood pressure 135-90. Hemoglobin seventy-five per cent. Blood count was 3,800,000 red, 8,000 white, polymorphonuclear 60. Urine negative.

Fluoroscopic examination showed much peribronchial infiltration at the hilus. The cardiac shadow was large, both right and left. The apex, peak shaped, merged with the diaphragm but could be made out on deep breathing. The heart was slow. The mediastinal spaces not very clear. I made a diagnosis of heart failure due to mitral stenosis with relative insufficiency and partial heart block.

After prolonged rest in bed and exhibition of large doses of digitalis, patient improved. Tonsils were removed and teeth corrected. Two months later patient got an attack of acute articular rheumatism involving the right elbow and knee joints with an inflamed throat. Large doses of salicylates afforded some relief but condition lapsed into a subacute state. Cardiac decompensation with auricular fibrillation set in and her urine showed albumin and casts and blood. Digitalis, diuretin and camphor served to control the situation. Patient began to mend and was comfortable. On April 10, 1924, patient was suddenly seized with severe pain in right leg with cramps in the calf and chills.

Examination of leg showed it white and cold below the knee, with rapidly setting in gangrene in the toes. A diagnosis of thrombus formation in the popliteal artery was made. The leg was amputated above the knee. Patient recovered from the operation, but died five weeks later from heart failure.

By way of summarizing, it seems obvious that Case I presents a condition of mitral stenosis which was probably purely valvular with little or no involvement of the myocardium.

Case II gives evidence of some degree of myocardial involvement characterized by arrhythmia and frequent attacks of paroxysmal tachycardia.

Case III shows a preponderance in involvement of the myocardium characterized by lost compensation with auricular fibrillation and partial heart block with secondary nephritis and thrombus formation.

A word or two as to the management of mitral stenosis: In a given case with few signs of heart failure, the diagnosis being established, the attention of the physician should be centered upon the conservation of the heart muscle. With that in mind, it becomes clear that all sources of infection must be located if possible and removed.

Teeth, tonsils and sinuses should receive consideration. The gastrointestinal tract should be closely surveyed, for we know not as yet what selective effect the toxins in the gastrointestinal tract may have upon the valves and myocardium. The possibility of colitis, chronic appendix, gallbladder disease, gastric ulcer, chronic constipation and pelvic disease should be borne in mind, and, if such condition is discovered, it should be judiciously treated. Digitalis, of course, is the drug par excellence in heart failure, and its effect in establishing equilibrium is permanent. But if the causative conditions prevail; the disease will progress despite the drug, with recurrent attacks of heart failure.

The patient should receive intelligent supportive treatment. A proper diet is probably the most important feature, especially in the presence of renal complications. Comprehensive and detailed instructions should be given by way of rest, exercise and hygiene.

With such management, I believe, that in some cases of mitral stenosis with valvular involvement, progressive myocardial changes could be prevented, and, in some cases, where the myocardium has become affected, further progress of the disease could be arrested and the life of patient prolonged.

Auricular Flutter

LOUIS FAUGERES BISHOP, M.D.
New York

Auricular flutter is a disorder of the mechanism of the heart beat in which the impulses governing contraction originate in some ectopic focus of the auricle instead of at the sinoauricular node at an extremely rapid rate varying between 200 and 350 a minute. Although the rate is rapid in this condition the rhythm is regular, differing in this respect from auricular fibrillation. On account of the extremely rapid generation of the impulses in auricular flutter the ventricles are unable to respond at the same rate and a type of heart block is developed wherein the ventricles beat at a rate of one quarter to one half that of the auricles. We thus get a two to one, three to one or four to one rhythm, as it is called, which can plainly be seen on the electrocardiogram. For example, suppose the auricles are contracting at the rate of 300 a minute and the ventricular rate is only 150 a minute we can see on the electrocardiogram two P waves for every Q R S-T complex; in other words, a two to one rhythm is present. It is important to note that the rhythm of the ventricles is also perfectly regular.

Digitalis is the specific remedy in this type of abnormal heart condition and it acts by first changing the flutter to auricular fibrillation and then normal rhythm may return.

It is important in the first instance to give enough digitalis to bring about these changes in a reasonably short period of time.

On account of its rather grave significance in most cases, it is important to recognize auricular flutter when present so that proper treatment may be instituted without delay. A positive diagnosis can be made only by the electrocardiogram but in a person suffering from cardiac failure with an extremely rapid though regular ventricular rhythm, the possibilities of the presence of auricular flutter should always be considered.

A rather typical example will now be outlined showing the importance of early diagnosis and treatment as a life saving measure.

Case.—A few days ago I received an urgent call to a distant city to see a lady fifty-one years old. I found her suffering from signs of cardiac decompensation with complete exhaustion. She was cyanotic and her liver and abdomen were distended, there being present a certain amount of ascitic fluid. It was said that she had had a very rapid heart for a long time; that two months before this time she had collapsed and since then had been confined to bed, and was extremely nauseated. Previously she had been well and unusually strong. Apparently no definite diagnosis had been made. It was casually remarked that her heart rate could not be counted, and it was, indeed, difficult to count but it proved to be 216 to the minute and regular. Digitalis had been given casually in the form of the tincture, ten to twenty minims at a time. Of course the situation was a desperate one and the nature of auricular flutter, which was more than likely present, and its specific treatment were duly explained. It was also mentioned that the administration of digitalis is not contraindicated when nausea is present in such a case, though in this instance it would be advisable to give it intravenously or intramuscularly.

The treatment of such a person without the presence of a cardiologically trained nurse or physician was, of course, a crude undertaking, since the proper use of digitalis without delay constituted the woman's only chance of recovery.

The advantage of a scientific knowledge of auricular flutter is the realization that the heart is not condemned as a whole, but the blame is to be placed chiefly upon the auricle where it belongs, and we seek to remedy the trouble at this source. The lady described above had evidently been treated under the impression that she was suffering from a rapid heart, symptomatic of some general disorder. The estab-

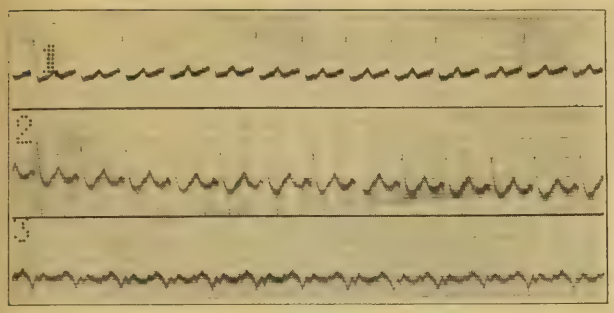

Fig. 1.—Auricular flutter untreated.

lishment of this distinction between symptomatic tachycardia and tachycardia of specific cardiac origin constitutes an important function of the cardiologist. Upon this differentiation must often depend the recognition of auricular flutter after an operation and it may dispel the fear of infection as the cause of a rapid heart. This often averts unwise surgical interference.

In this patient two ampoules of digifoline were at once injected intramuscularly, followed every four hours by a single ampoule, and instructions were given that this treatment be carried on until eight ampoules in all had been injected, at which time it

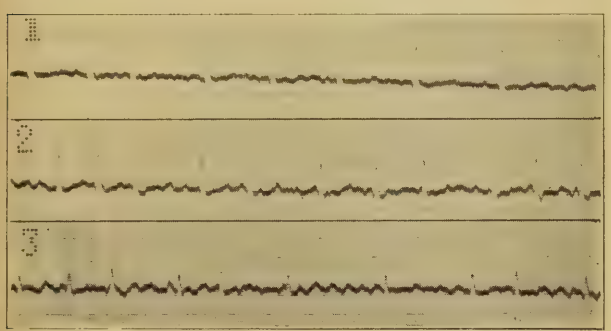

Fig. 2.—Auricular flutter two days after digitalis treatment was instituted, showing typical auricular fibrillation.

would be advisable to have another conference concerning the problem of her cure. It was predicted that, if things went well, the heart would become irregular and assume the classical picture of fibrillation—first, a rapid irregular pulse and later a slow irregular pulse, and finally the resumption of normal rhythm. At about the time the eighth ampoule had been given, representing twelve gr. of digitalis in all, the pulse rate fell to 140 and was completely irregular. The dose was then reduced to three ampoules in twenty-four hours with the advice that

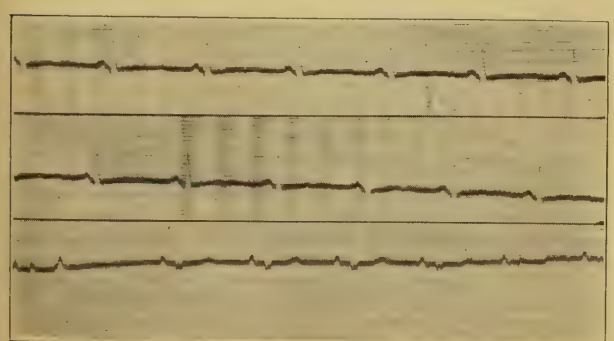

Fig. 3.—Three days later showing normal rhythm.

when the heart rate fell to 90 this dose should be further reduced. Coincident with the control of the heart the whole clinical picture changed. The nausea and vomiting disappeared, the woman gained in strength and developed a voracious appetite. In this instance the heart, arteries and kidneys were appar-

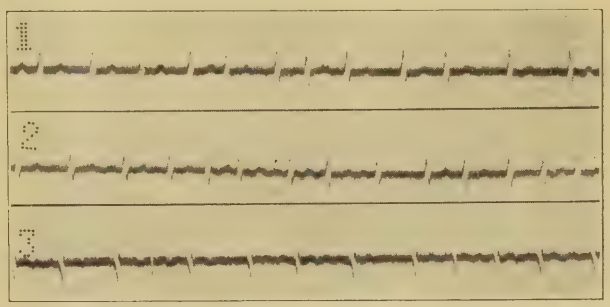

Fig. 4.—A later picture of the patient in the case discussed in the article showing auricular fibrillation.

ently fairly sound and there is no reason why this person should not enjoy fairly good health with a controlled fibrillation or possibly with complete restoration of rhythm.

The practice of cardiology is fraught with many perplexities and discouragements. So it is with keen joy that one is able to record an instance where the recognition of the true nature of a disorder of the heart resulted in as brilliant an achievement in the saving of human life as if a surgeon had operated upon a ruptured appendix or a bleeding ectopic pregnancy. Great credit is due Sir James MacKenzie and his pupils who have given to the world this precise knowledge of the heart beat without which this woman would have lost her life. Unfortunately it was not possible to get electrocardiographic records of this case of auricular flutter when first seen, but for the sake of reference, records are herewith in-

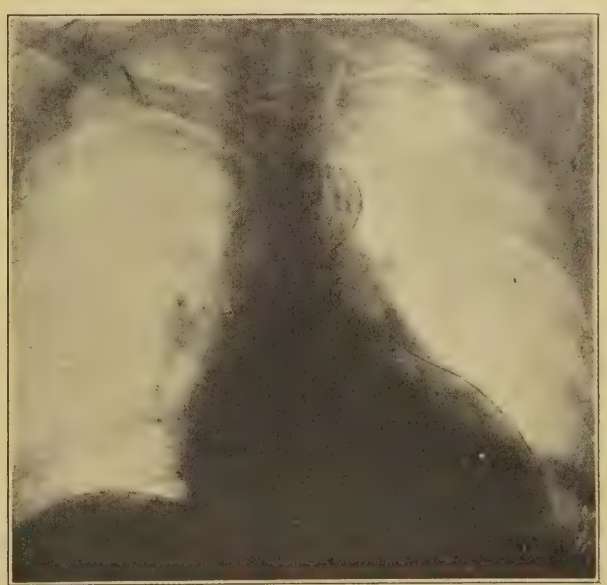

Fig. 5.—X ray of the heart of the patient shown in Fig. 4.

cluded of a gentleman showing a similar condition, also an x ray of the patient's heart and an electrocardiogram taken from her at a later date, when she was fibrillating, but up and around and quite happy.

109 East Sixty-first Street.

The Direct Treatment of Heart Failure*

EDWARD E. CORNWALL, M.D., F.A.C.P.
Brooklyn, New York

In treating heart failure we have to lessen the work of the heart and improve its nutrition by giving rest, removing sources of toxic irritation and regulating diet and exercise, and also often we have to improve its action in a more direct manner. The agents used in this direct treatment are generally classed as heart stimulants, but it seems logical to separate them into two groups, the first comprising those which act directly on the heart muscle to increase its intrinsic property of contractility and allied property of tonicity, and the second comprising those which improve the heart's action by exciting activities that facilitate the proper functioning of the heart or nullify or modify activities that interfere with its proper functioning; and to reserve the term heart stimulant for those in the first group, applying the term heart regulator to the others. This differentiation of heart stimulants and heart regulators has clinical significance because in the direct treatment of heart failure we find that some cases require particularly increase in contractile energy of the heart muscle, while others call for removal of the impediment of an arrhythmia or for special activity of the nervous mechanism controlling the heart. Let us briefly review some of the more important of these agents.

DIGITALIS

We will speak first of digitalis, which is the most celebrated of them all, the most extensively used, and we might add, the most abused. Digitalis has been known to medicine for a long time, and has been the subject of much clinical and laboratory study, but our knowledge of its action is not altogether satisfactory, and differences of opinion exist regarding it. That it acts in two ways, directly on the myocardium and indirectly through stimulation of the vagus nerve—directly to increase the excitability and depress the conductivity of the myocardium, and indirectly through stimulation of the vagus to depress the myocardial functions generally—is pretty well established; but that it has a direct effect on the myocardium to increase its contractility and tonicity remains in dispute. Stevens says that digitalis increases contractility and tonicity (1), and this opinion seems to be held by many; but Lewis (2), Mackenzie (3), Vaquez (4) and others appear unable to find that it has any such direct effect. Hale White says that it increases contractility in frogs but not in mammals, and that in mammals poisoned by digitalis the heart stops in diastole, and he suggests as an explanation that the depressing vagus effect predominates in mammals (5).

Accepting, subject to revision on further evidence, the negative decision of the disputed question of the direct action of digitalis on contractility and tonicity, we find that this drug conforms to the definition of a heart regulator rather than to that of a heart stimulant. Acting directly on the myocardium and indirectly through the vagus, it lessens the ability of the heart muscle to transmit contractile impulses, and this effect, intensified by specific doses to the extent of producing partial heart block or notably delayed conduction, can free the ventricles from the impediment to their proper action presented by the arrhythmias known as auricular fibrillation and flutter. It may also be possible for it to act beneficially in some cases of heart failure with normal rhythm when, in nonspecific doses, it slightly slows the heart and prolongs its diastole and relaxes its musculature; thus favoring fuller filling of the ventricles, increased circulation in the coronary arteries and a larger output from the ventricles; provided that the ventricles are in a condition to respond to the stimulus of increased blood supply and distention; but if by reason of intrinsic disease the ventricles are not able to respond, then the giving of digitalis makes for a pathological dilatation or in increase of an existing dilatation, as has been pointed out by Vaquez. This action of digitalis to improve the circulation by relaxing the heart appears to be a justification of its so-called tonic use. Its regular or specific use would seem to be limited to cases of heart failure with auricular fibrillation and flutter, in which it is given to relieve the ventricles from the impediment of the arrhythmia. But in cases of auricular fibrillation with much degeneration or dilatation of the ventricles, the release of the ventricles from the impediment of the arrhythmia may not be sufficient to bring about notable improvement of the circulation; and this observation, which has been made, favors the view that digitalis does not directly increase contractility. In conditions of normal cardiac action digitalis in doses within therapeutic limits appears not notably to modify the action of the heart or the circulation, probably because the natural compensatory mechanism nullifies the disturbing effects of the drug. In some cases with regular rhythm the administration of digitalis has been observed by the author to be followed by lowering of the blood pressure and increase of the pulse rate. The whole picture of digitalis action seems to be dominated by its vagus effects.

STROPHANTHUS

Strophanthus has advanced to the front among cardiac remedies in comparatively recent years, but it has not yet succeeded in becoming established as an institution, like digitalis. Its action is thought by many to be the same as that of digitalis, and many consider it a sort of inferior digitalis; and James Mackenzie as late as 1921 said that he could see no difference between the actions of the two drugs (6). But there are good reasons for considering strophanthus a heart stimulant as above defined, that is, as acting directly on the heart muscle to increase its contractility, and thus differing from digitalis. It also appears to act directly on the myocardium to increase excitability and depress conductivity, in these respects resembling digitalis. It apparently does not influence the heart through stimulation of the vagus,

*Read before The Medical Association of the Greater City of New York, March 15, 1926, and the American Therapeutic Society, Philadelphia, June 12, 1926.

in this respect differing radically from digitalis. Support of the statement that it does not act on the vagus is suggested by a recent observation of Cushny to the effect that while a rapid heart slowed by digitalis recovered part of its former rate after administration of atropine to block the vagus, a heart slowed by strophanthin showed no increase of rate after administration of atropine (7). In regard to the statement that it directly increases contractility may be quoted Vaquez, who says that strophanthin becomes "fixed in the myocardium after the manner of a stain or a toxin" (8), in consequence of which the contractile power of the muscle is increased. With lethal doses the heart is found rigidly contracted and empty. Strophanthin is rapidly used up in the body and cannot be recovered in any of the excretions. Vaquez calls it the "heart medicine par excellence." Hare says that strophanthus acts as a stimulant to the heart muscle, but does not slow the heart by an action on the vagus (9). It apparently acts by contact and leaves the heart in systole after death from its use.

Clinical observations in an extensive use of strophanthus during many years incline me to accept the view that strophanthus is a heart stimulant and acts differently from digitalis. More than twenty years ago, in 1905, I recorded my opinion that "in uncompensated valvular disease in which the prognosis is bad as regards recovery of compensation strophanthus acts better than digitalis. And in dilatation from any cause where the prognosis is bad strophanthus is usually better than digitalis" (10).

LESSER HEART REMEDIES

Besides the two agents above mentioned there are others which are used in the direct treatment of heart failure, most of which belong in the group of heart regulators. Among these "lesser" heart remedies the following are selected for notice.

Quinidine is a heart regulator which seems able to remove the impediment to the proper action of the ventricles presented by auricular fibrillation in a considerable proportion of the cases, but there are serious drawbacks to its general use.

Atropine is a heart regulator which can block the vagus, but its usefulness in the treatment of heart failure is comparatively small.

Strychnine has a well deserved reputation in the treatment of heart failure, especially in cases occurring in acute infections and in ambulant cases with restricted activity. It is apparently a heart regulator which acts by stimulating nerve centres and increasing the secretion or the effectiveness of adrenalin. Its most particular use is in conditions with low blood pressure.

Caffeine has been considered a heart stimulant, but proof that it directly increases myocardial contractility seems to be lacking. It variously affects the rate of the heart through stimulation of the vagus and sympathetic systems, and seems sometimes to raise the blood pressure after a preliminary lowering of it. It also stimulates respiration. It notably stimulates the higher cerebral centres, increasing mental activity in moderate doses and causing confusion of thought in excessive doses; and it stimulates the kidney excretion. On account of the disturbances of the nervous system which it produces, it should be used with caution.

Adrenalin is a vasoconstrictor with an established reputation among heart regulators, although its general usefulness in heart failure is not as great as might be inferred from the definiteness of its action.

Nitroglycerin and amyl nitrite are vasodilators, and as such are capable of lessening the load of the laboring heart, and thus appearing as heart regulators, but they are rarely used for exactly that purpose, as Nature in most cases can make such adjustments along the line of their action for that purpose as the circumstances require or permit. The indications for the use of nitroglycerin are chiefly to relieve distressing or dangerous symptoms due to local arteriosclerosis or spasm, and to lower the general blood pressure when its continuance at the existing height threatens destructive accidents to the circulatory apparatus, particularly the arteries. It may help to free the circulation in vitally important regions of the body, as the heart and brain, when the supplying arteries are unduly contracted and especially when high blood pressure coexists. The main contraindication to its use is low blood pressure, and in general, it should not be given if the pressure is below the normal for age and condition: the necessity for maintaining the existing pressure may be more urgent than the indication to relieve the load of the heart.

Calcium, being necessary to muscular contraction, can be considered a heart stimulant when administered in cases of calcium deficiency, which should be looked out for and guarded against in cases of heart failure.

Morphine should be included with the agents employed in the direct treatment of heart failure, being a heart regulator through its sedative effect on the nervous system. In certain phases of the condition it is indispensable. It is of great value in pulmonary edema. Given in small doses at regular intervals with digitalis or strophanthus, or in larger single doses, it may be effective in relieving dyspnea. When arteriodilators fail to relieve in angina pectoris, then recourse must be had to morphine. It alone can relieve the prolonged agony so often present in the final stages of progressive heart failure.

A mechanical procedure which has a place with the heart regulators used in the direct treatment of heart failure, particularly in the acute failure of the right heart, is bleeding.

PRACTICAL USE OF HEART STIMULANTS AND HEART REGULATORS

In speaking of the practical use of heart stimulants and heart regulators in the direct treatment of heart failure, I realize the impossibility of presenting the subject in a systematic and conclusive manner: because of the great variety of indications for these agents presented by the different cases, because the use of these agents has not been standardized, and because of the differences of opinion that exist regarding their use: there are those who use digitalis for a direct heart stimulant and always in full, specific doses; there are those who do not use strophanthus at all, or if they do, try to use it like digitalis and always in large doses; and there are those who speak slightingly of strychnine: and there is diversity of opinion as to dose and administration, some believing that digitalis should be given regularly in massive doses to produce quick digitalization, while others hold that it is a better procedure to secure

therapeutic saturation with the drug more gradually, by the use of smaller doses longer continued, in order to safeguard against excessive toxic action being precipitated by pathological changes in the heart. In view of these confused conditions I shall not attempt to discuss the subject in general or the opinions of others, but will confine my remarks to a few words on the treatment of certain types of heart failure from the viewpoint of my own experience and opinions.

Cases of heart failure can be differentiated to a certain extent into types, as acute, recurrent and progressive; and as predominantly of the right heart and of the left; and as due to myocardial weakness or to an impeding arrhythmia, or to nervous or vascular disturbances. It is a matter of practical interest that failure predominantly of the right heart is characteristic of mitral valve disease, while failure predominantly of the left heart is characteristic of aortic valve disease and conditions producing high blood pressure; and that in the former group of cases auricular fibrillation is likely to develop, while it is much less common in the latter: for which a reason might be found in the fact that the comparatively thin walled left auricle is under special strain in mitral disease and thus predisposed to the changes which bring about auricular fibrillation. In the right heart failure of pneumonia, however, the myocardial weakness develops in the heart muscle itself or against a resistance in the pulmonary circuit, and the left auricle is not subjected to the same strain as in mitral disease; and auricular fibrillation is not so regularly seen in this form of right heart failure. And in the failure due to acute and chronic degenerations affecting either ventricle auricular fibrillation is not so regularly seen.

A commonly observed type of right heart failure is that of mitral stenosis with auricular fibrillation. In the treatment of the cases of moderate severity digitalis is given to the extent of producing beginning toxic symptoms. The author gives the equivalent of fifteen minims of an active, standardized tincture three or four times daily until toxic symptoms appear, which is usually not later than the fifth or sixth day and may be earlier, depending on the pathological changes in the myocardium; and then, either immediately or after an interval of rest, the drug is continued with a daily dose of fifteen or twenty minims, or whatever dose proves necessary to maintain the degree of saturation suitable for the case.

In the severe cases of right heart failure, especially those with much dilatation, occurring in mitral disease, strophanthus is the preferred remedy, at least at first. I usually begin with giving an amorphous strophanthin in doses of 1/250 gr. or less every four hours until relief is obtained or a stated number of doses has been given, and continue it in doses of 1/500 gr. or less every four hours. After improvement has taken place digitalis may be tried in place of the strophanthin, and continued if the results are favorable. But digitalis sometimes fails to improve the condition, especially if there is much myocardial degeneration and dilatation, as in the following case, in which the patient did better on strophanthin throughout.

Case I.—A woman of forty-seven, with a double mitral lesion, had recurrent attacks of right heart failure which were successfully treated with strophanthin as above described, digitalis having been tried without benefit. In one of these recurrent attacks she had severe pulmonary congestion with pneumonia of heart disease, great enlargement of the liver, extensive edema of the lower extremities and marked renal congestion. She was confined to her bed for seven months, but finally recovered a sufficient degree of cardiac compensation to be able to go up two flights of stairs without distress and to take a trip to Venezuela and back. She maintained her compensation for five years by taking three or four times daily under the tongue 1/500 gr. of the strophanthin.

In progressive failure of the right heart in mitral disease strophanthin and digitalis may each be tried, and the one which seems to produce the best results continued, but strophanthin should be tried first, as it has no cumulative effect and does not interfere with the subsequent giving of digitalis. If the heart has already been digitalized, the administration of strophanthin is dangerous, because the actions of the two drugs overlap in the matter of depressing conductivity, and the strophanthin might increase the depression of conductivity already present so as to precipitate severe heart block.

In failure of the right heart occurring in the acute infections strophanthin may be given, and when the condition is extreme, it should be given in special dose, as in the following case.

Case II.—A young man in the fifth day of a lobar pneumonia jumped out of bed in delirium and acute right heart failure developed with dilatation, very rapid and feeble pulse and extensive pulmonary edema. He was given 1/100 gr. of the amorphous strophanthin by intramuscular injection and recovered.

In any case of acute heart failure showing dangerous symptoms the dose of the strophanthin may be 1/100 gr. and it is best given intramuscularly or intravenously; but this dose is exceptional and should not, as a rule, be repeated inside of twenty-four hours.

Along with the use of strophanthin in acute failure of the right heart, bleeding would seem to be good treatment in very severe cases with extensive pulmonary edema and cyanosis; and the use of morphine in the treatment of acute pulmonary edema recommends itself.

Failure of the left heart more regularly than that of the right calls for strophanthin in preference to digitalis, auricular fibrillation being much less common in left heart failure. It has been noted that in total cardiac failure the failure of the left heart is likely to predominate, especially when the failure develops suddenly. In chronic progressive failure of the left heart, such as is seen in aortic valve disease and in conditions of long continued high blood pressure, strophanthin is an effective remedy, given in doses graded to suit the degree of the heart failure; and in ambulant cases which are on the verge of failure, it may be of great value as a safeguard, given in small, continued doses, as 1/2000 gr. or 1/1000 gr. of the amorphous strophanthin every four hours, sublingually.

In the heart failure of acute and chronic myocarditis without auricular fibrillation or flutter, strophanthin is generally indicated. In these conditions strychnine is often useful as an adjuvant; and in conditions of potential failure the strychnine may be

given before the strophanthin is needed; strychnine is especially useful for combatting the tendency to low blood pressure; it should be given, as a rule, in doses not exceeding 1/60 gr. every four hours.

My plan of treatment for the failing heart of pneumonia includes the use of strychnine sulphate, 1/60 gr., every four hours at the first sign or suspicion of heart failure, or if the blood pressure is extremely low; and if the failure becomes evident, of the strophanthin in addition, usually in doses of 1/1000 gr. to 1/500 gr., every four hours, and in severe cases, of 1/250 gr. every four hours. In acute cardiac dilatation a single dose of 1/100 gr. may be given as before described. Calcium chloride or an equivalent calcium salt, is given to the amount of ½ dr. daily.

That a definite action on the heart and circulation can be secured by what seem to be very small doses of the amorphous strophanthin has been noted by the author. An elderly physician with influenza and a very low blood pressure and signs and symptoms of potential heart failure while in bed, testified that he could feel the good effects on his heart and circulation of 1/2000 gr. taken every four hours sublingually.

I wish especially to emphasize the necessity of giving strophanthus in proper doses. It was only after he had learned the proper doses that he was able to get the very good results from it which he is able to report. The dose of this drug is not, as is that of digitalis regularly specific and measured by the lower limit of toxic effect, but it varies according to the degree of myocardial failure relative to the circulatory requirement in each case. It may well be largely due to the fact that many of those who have used strophanthus have given it in excessively large doses, following, indeed, recommendations in the text books, and to the fact that many have tried to use it like digitalis, that this most valuable remedy has failed to secure the universal appreciation to which its merits would seem to entitle it. The best preparation is strophanthin, of which there are two main varieties, amorphous and crystalized; and it is well to use one strophanthin regularly and to become familiar with its dosage; and particularly important is it not to use a crystallized strophanthin in the same dose that has been found proper for an amorphous strophanthin. It should always be given sublingually, hypodermically, intramuscularly or intravenously; in a large proportion of cases sublingual administration is satisfactory; it should not be given by mouth to be swallowed. It is also possible to get good results with the tincture, as I have abundantly observed in the past; but with strophanthin the tincture may be discarded.

Among those who have done much in recent years to advance the therapeutics of strophanthin is Henri Vaquez of Paris. He prefers the crystalized strophanthin known as ouabain, which he gives in acute heart failure as follows. He gives intravenously, ouabain, 1/240 gr. every twelve hours for three doses, and after an interval of twenty-four hours a fourth dose, so that the patient gets one milligram in forty-eight hours. In chronic cases he may give one fourth of a milligram daily for eight or ten days.

In concluding I select for emphasis the following statements:

As a guide to the use of digitalis in heart failure laboratory experimentation, especially on animals, cannot altogether be trusted, as Mackenzie has said, because pathological changes in the human organism can modify the effects of the drug and discredit inferences from such experimentation; clinical experience must largely determine its practical use.

Clinical experience has shown that digitalis is a remarkably effective remedy in conditions of heart failure with dropsy, and a large proportion of these cases suffer from auricular fibrillation. And we have a reasonable explanation of how digitalis acts to improve the circulation in auricular fibrillation, viz., by removing through depression of conduction the impediment to proper ventricular action presented by the arrhythmia.

That digitalis by direct action increases myocardial contractility and tonicity in humans has not been satisfactorily proved; the contrary would seem to be an inference from the fact that with a lethal dose the heart stops in diastole. That it can improve the circulation in certain cases with normal rhythm indirectly, however, by relaxing the cardiac musculature and thereby favoring increased coronary circulation, fuller filling of the ventricles and an increased output from the ventricles seems probable.

When given for relief in auricular fibrillation the dose should be specific, that is, pushed to the production of beginning toxic effects.

There are three factors which determine the effects of digitalis, the size of the dose, the size of the patient's body, and the pathological conditions in the patient's body, particularly his myocardium; the last factor would seem to make impossible absolute standardization of the specific dose: a dose that would produce mild toxic symptoms in one patient might produce severe toxic symptoms in another patient of the same size whose myocardium was more diseased.

Strophanthus is an effective and powerful heart stimulant which acts, it would seem, directly on the heart muscle to increase its contractility, and not at all on the vagus mechanism. It parallels digitalis in action in the matter of increasing the excitability and depressing the conductivity of the myocardium, but it differs from digitalis in action so radically in other respects that it cannot be considered as a substitute for that drug, but rather as an independent ally, useful in many cases of heart failure where digitalis is not indicated or is less efficient. It is useful, indeed, wherever a direct heart stimulant is needed. But to get good results from its use it is essential that the dose be properly adjusted: the ideal dose is the smallest practicable, and excessively large doses should be avoided. The best preparation is strophanthin, and it should be administered sublingually, hypodermically, intramuscularly or intravenously. A small percentage of patients show a gastrointestinal idiosyncrasy to strophanthus.

The Pupil as an Index of Activity in Cardiac Lesions

JOSEPH BYRNE, A.M., M.D., LL.D.
New York

Since publishing the results of my studies made at Fordham University on the Afferent Relations of the Skin and Viscera to the Pupil Dilator Mechanism (1) I have had abundant opportunity of verifying clinically my experimental findings. In unilateral somatic lesions below the level of the umbilicus the contralateral is the smaller pupil so long as the patient is quiescent and free from pain but it at once becomes larger than its fellow when the patient becomes disturbed or is in pain. In one sided somatic lesions above the level of the umbilicus (trunk, arm, head or neck), the pupillary changes are observed in the homolateral eye. In the viscera one sided lesion induces pupillary changes like those found in somatic lesions, the crossed or uncrossed effects being determined by the primitive afferent nerve supply. If this latter be preponderately derived from one side of the spinal cord and from a level predominantly cephalad of the umbilicus (tenth thoracic segment) the effects are uncrossed, but if the one sided nerve supply be originally derived from a level predominantly caudad of the umbilicus the effects are crossed. In paired organs such as the lungs the homolateral pupil usually shows the positive (relative dilatation) or negative (relative constriction) phase of what the author has named the pseudoparadoxical dilatation phenomenon (2). In the heart the chambers are really paired organs. Hence lesions of the right ventricle evoke the phenomenon in the right pupil and lesions of the left ventricle and aorta evoke it in the left pupil. In all sorts of cardioaortic disease the phenomenon may be observed. Taken in conjunction with the reflected pain and hyperalgesia which always accompany inflammatory changes in the cardioaortic structures I have found the pupil phenomenon to be, not only a reliable, corroborative, localizing, diagnostic sign, but also a safe guide in therapy. More especially has it been found to be a reliable index in the matter of regulating such important therapeutic measures as exercise and rest. Thus where there is question as to the activity or nonactivity of the lesion the negative phase (relative constriction) plus the absence of spontaneous reflected pain or of marked hyperalgesia would point to nonactivity whereas the positive (relative dilatation) phase plus the presence of spontaneous reflected pain or of acute hyperalgesia would indicate an active lesion. The reflected pain and deep hyperalgesic areas most intimately associated with cardioaortic disease are (on the ventral aspect) those thoracic areas bounding the nipple region, viz., the third and fourth areas cephalad of the nipple in a line drawn from the latter to the middle of the clavicle, the fifth area just lateral of the nipple, and the sixth area just caudad and mesial of the nipple. Areas corresponding to these are also found on the dorsal aspect (Fig. 1). In an active lesion the spontaneous reflected pain is usually one sided and often associated with a more or less intense hyperalgesia (always bilateral) both superficial (tested by the dragged pinpoint or finger nail, etc.) and deep (tested by digital pressure). More usually, however, the hyperalgesia is of the deep variety, the superficial hyperalgesia being absent or confined to the regions overlying the deep hyperalgesic areas. In quiescent lesions the superficial hyperalgesia is altogether absent and the deep hyperalgesia mild and elicitable only by comparatively heavy pressure. In some instances of reactivated lesions, e. g., in "mitral disease," I have seen the left pupil exhibit both phases of the pupillary phenomenon merely on change of posture, thus the active phase (relative dilatation) was present when the patient was sitting or standing and the negative phase (relative constriction) when the patient was lying down. In these cases the left pupil could be made smaller or larger than the right merely by having the patient lie down or sit up. This variation of the phenomenon with changes of posture well illustrates the intimate functional relations between the pupil dilator mechanism and the heart and aorta. The reflected pain and hyperalgesia are also affected by posture and though they do not register their changes as dramatically as does the pupil, they register them effectively.

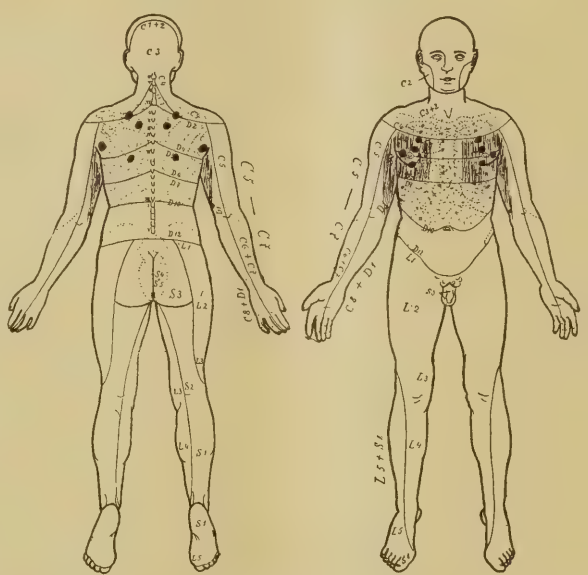

Fig. 1.—Reactivated mitral disease with beginning decompensation. Heavy spots, deep hyperalgesia (on left, cardioaortic areas of reflected pain); linear shading, intense superficial hyperalgesia (fused pulmonic, cardioaortic and gastric areas). In recumbency left pupil smaller than right 3.0: 2:5 mm, but larger 3.0: 3:5 mm when sitting or standing.

Thus in almost any cardiac condition in which reflected pain or hyperalgesia is a feature this tends to disappear in a short time after the patient has been put to bed. And conversely where it has disappeared after a period of rest it tends to reappear when work or exercise is resumed too early or is too arduous or

prolonged; or where the activity period is out of proportion to the rest period, i. e., exceeds the optimum. In cases in which decompensation has set in the reflected pain and hyperalgesia tend to abate but coincident with this the negative (relative constriction) phase of the pupil phenomenon gives place to the positive (relative dilatation) phase. Where compensation is good and in cases with well maintained or even abnormally high blood pressure, the reflected pain and hyperalgesia are usually present only when the patient has been exerting himself or has been unduly excited or is in pain. In these cases the phenomenon follows the general rule, viz., in quiescence the pupil exhibits the negative (relative constriction) phase and in activity the positive (relative dilatation) phase.

In conclusion it must be emphasized that both the pupil phenomenon and the reflected pain and hyperalgesia are merely good corroborative localizing signs of disease and by no means to be depended upon exclusively as to the existence or non-existence of disease in a particular viscus. These matters will be more fully discussed in a communication to follow this preliminary communication.

Cardiazol, a Heart Stimulant

GEORGE L. WALDBOTT, M.D.
Detroit, Michigan

A great number of investigators have been working in recent years to determine the value of camphorated oil as a heart stimulant. Lately it has been shown that it is without any effect whatsoever if administered in its ordinary form. Of this fact Heathcote (1), Marvin and Soifer (2) have given conclusive evidence by clinical observation and by animal experiments.

On the other hand, we cannot overlook the fact that good results have occasionally been obtained with this drug. We know that camphorated oil, when brought in direct contact with an animal heart damaged by chloroform, cholin, muscarin, chloral hydrate and other substances, increases the force of the systole and reduces the pulse rate (Cushny, 3).

The reason for this apparent contradiction has been brought out by Schmiedeberg and Meyer (4), who found that camphorated oil is slowly absorbed after subcutaneous injection. As soon as it reaches the blood stream the body tends to inactivate and to eliminate it immediately. It becomes oxidized and combined with glycuronic acid and leaves the organism with the urine as camphor glycuronic acid. Therefore the concentration in the heart necessary for its effect is very seldom reached, and thus the action of the camphorated oil, if any, is very uncertain.

The first attempts to obviate this difficulty were made by Leo (5), who gave camphorated oil intravenously. However, the absolute insolubility of camphorated oil in water necessitated very large infusions of water and therefore prevented the practical application of this method.

In order to obtain a camphorated oil which would be readily soluble in water, Gottlieb and Schulemann (6) produced synthetically a preparation called hexeton or homocamphin. This drug, when given intravenously, is rapidly absorbed and it is maintained that it affords sufficient effect. In its chemical structure it resembles very closely camphorated oil. However, in order to facilitate its solubility it has to be given with twenty per cent. sodium salicylate solution.

Schmidt (7) has tried to eliminate this disadvantage in producing a new preparation called cardiazol. It is obtained by a new method of synthesis by the action of two molecules of hydrazoic acid on cyclohexanon. The preliminary experiments for its production have been made at the Chemical Institute of the Swedish University of Abo, Finland. In its chemical formula Cardiazol differs considerably from camphor. It is a combination of the nitrogen containing tetrazol ring with the pentamethylene group and therefore not related to the volatile oils of the terpene group.

It has been applied recently in European clinics, and the latest reports (Krehl, 7, and Hemmerling, 8), warrant further clinical trials. Its chief indication of application is cardiovascular collapse. It is also asserted that auricular fibrillation and angina pectoris have been benefited by this drug.

The pharmacological studies done by Hildebrandt (7) revealed the following facts: When administered subcutaneously to an animal it is instantly absorbed and exerts its action on the heart within a few minutes. On the frog heart, damaged by chloroform, it increases the amplitude of the systole and slows down the pulse rate. If the heart is previously intoxicated by strophanthin, cardiazol regulates the rhythm. Besides, it stimulates the cardiovascular centres in the medulla and thus increases the blood pressure.

Since only a small trial quantity was at my disposal, only three case reports can be given.

Case I.—B. A., a man fifty-four years old, was seen in auricular fibrillation which had developed in the course of a right side bronchopneumonia. Examination showed marked hypertrophy of the heart, the apex rate being 172, pulse 135, perfectly irregular in rhythm and force, respiration 39, blood pressure 78-47. Marked cyanosis and dyspnea were present. Eight minutes after the subcutaneous injection of cardiazol the patient felt much stronger, his respiration decreased to 32, the heart rate was still irregular, but decreased to 158. Blood pressure rose to 93-54. Digitalis was started later and administered

every four hours. The injection of cardiazol was repeated the next morning when the apex rate was 149. About eight minutes after this injection the heart became regular, no pulse deficit being present. The blood pressure rose to 110.

CASE II.—J. T., a man twenty-nine years old, with bronchial asthma complicated by chronic myocarditis, showed all signs of pronounced lung edema following a three days' asthmatic attack. The heart beat was 197, the pulse could scarcely be felt. The blood pressure was 52 to 31. He expectorated frothy sputum. He showed cold perspiration. Moist râles were heard throughout both lungs, and considerable impairment over both bases of lungs was present. Adrenalin, which had been given frequently, was of no more value. One c. c. of cardiazol administered subcutaneously checked the expectoration of frothy sputum, increased the blood pressure to 65, brought down the pulse rate to 155 within ten minutes. The same day two more injections were given by the nurse, from which considerable subjective improvement resulted until the administered digitalis became effective.

CASE III.—Mrs. R. had had septic tonsillitis, was seen in a stage of pronounced vascular collapse. The respiration was 42, pulse 158, blood pressure 85-32. She was delirious and suffered considerably from dyspnea. Fifteen minutes after the subcutaneous administration of cardiazol the patient felt much stronger, sat up in bed, pulse was 122, and less frequent. Blood pressure 95-47.

SUMMARY

Cardiazol, a cardiac stimulant, has been tried in three cases. The results call for further clinical studies.

Suppuration of the Nasal Accessory Sinuses as a Portal of Entry of Infection in Diseases of the Heart

WILLIAM SPIELBERG, M.D.
New York

Ever since the infective character of endocarditis has been fully recognized and studied by Winge, Koster, Koch and others, the medical world has been on a constant look out for portals of entry of infection or socalled foci of infection.

With the recognition of the important rôle played by the mucous membrane as a portal of entry of microorganisms in diseases of the heart, came the researches which led to the establishment of the alimentary canal and the genitourinary and respiratory tracts as the chief portals of entry of infection.

The alimentary canal is considered the most common portal of entry of infection. In the mouth the alveolar abscess and necrotic bone changes associated with dental caries are foci of infection. The tonsils have been definitely proved to be responsible for a great many cases of heart disease, particularly in children where we not infrequently meet with cases of endocarditis without recognizable cause. Infections of the bile passages are held responsible for a large number of infections. The appendix although often looked upon as a portal of infection is thought to be an infrequent and even rare focus of infection.

In the genitourinary tract, gonorrhea, prostatitis, cystitis and suppurative processes of the kidneys are common foci of infection.

In the respiratory tract, several primary foci of infection have been recognized; they are the suppurative lesions of the nose and the paranasal sinuses, affections of the larynx and trachea and bronchiectasis. Pneumonia has been recognized as a common cause of heart disease, while suppuration of the pleura is a rare cause.

In the following paragraphs I shall confine my discussion only to the relationship of infections of the nasal sinuses to heart disease and the rôle played by them as a portal of entrance of infection.

Although the importance of suppuration of the nasal sinuses has long been recognized as a focus of infection in diseases of the heart, it is surprising to find from a close survey of literature, that comparatively little has been written on this subject.

Osler (1) refers to the suppuration of the nose and the adjacent sinuses as primary foci of infection in the etiology of acute valvular disease, but does so in a very superficial manner. He, however, stresses the importance of the tonsil as taking the first rank as a source of infection.

In a recent paper Dr. E. Ross Faulkner (2) discusses focal infections in the nasal sinuses. He points out that as foci of infection, the nasal sinuses are extremely frequent, far more frequent than members of the profession are prone to realize. He furthermore says there is no part of the body where a focus of infection may be more securely hidden from detection of the casual observer. It is of no little interest to note the statement by Faulkner that positive blood cultures can be obtained in many cases of acute sinusitis. He mentions a case of meningitis with streptococci in the spinal fluid from a sinusitis,

in which recovery took place after a radical operation on the sinuses.

Joseph W. Miller (3) reports three fatal cases of cardiac disease in which postmortem examination of the nasal sinuses revealed an empyema of one or both maxillary sinuses that was not detected before the patients died. Miller asserts that the involvement of the maxillary sinuses may have given rise directly or indirectly to the cardiac disease.

Daniel S. Dougherty (4) in a recent paper speaks of the nose and paranasal sinuses as sites of foci of infection likely to lead to rheumatism and heart disease.

During the past five years I have had the opportunity of examining and studying a very large group of cases at the clinics of the Beth Israel and the Midtown Hospitals and in private practice. The patients were studied carefully by clinical examinations, laboratory tests, x ray and antroscopic examinations.

It would not at all be exaggerating to state that practically every patient examined showed evidences of sinus infection in some form or another. Only very rarely could we say with any degree of certainty that a case was absolutely free from a diseased process in the sinuses. In antrum infections particularly, where a direct inspection of the lining mucous membrane was made possible by means of my antroscope, were we able definitely to differentiate pathological from nonpathological conditions. By this aid we were also able to study and distinguish all grades of polypoid degenerations, from the very early thickening to the advanced polypoid degeneration of the mucosa lining the sinus.

The x ray examination was a great help to us in so far as deciding whether a sinus was diseased or not. A cloudy plate, however, was found to be no indication of the character of the lesion present. An acutely congested mucosa of an antrum gave a marked cloud on the x ray plate, while extensive polypoid degeneration gave at times a slight diminution in the illumination, the latter depending on the amount of air present in the sinus and whether the natural opening was patent.

In spite, however, of the predominance of sinus disease we infrequently met with a frank or socalled closed empyema of a sinus. Open or discharging empyemas were more frequently met with, but proportionately were also rather infrequent.

In its relation to cardiac disease it is interesting to note that the number of cardiacs found among the patients examined was very negligible. In my private practice I have collected only three cases of cardiac disease associated with sinus infection, where the latter appears to be directly associated with the cardiac pathology, and possibly the focus of infection causing the heart trouble. I have also collected a group of cases with empyema of one or more of the sinuses in the same person where there is not the slightest suggestion of heart disease present.

The liability of infection does not therefore appear to depend on the degree of involvement or the number of sinuses involved, but on the virulence of the organism causing the infection, since certain bacteria are more prone to excite disease than others.

Sinus infections although widespread among children are rarely associated with rheumatic infection and endocarditis or other forms of heart disease. The same holds true with infections of the tonsils; although universal in childhood, they are only occasionally associated with heart disease. The same holds true also with many other infections which we carry about with us, without showing any manifestations of disease.

We are therefore inclined to reason that an infected sinus is but a link in the chain; the sinus harboring germs that will directly or indirectly cause a cardiac lesion, and in only a few presenting positive manifestations.

One cannot help feeling that we are still in the dark in determining the precise circumstances and pathways through which germs will travel and terminate in an infection of the heart in a given case.

The following is a brief report of three cases of sinus disease associated with heart trouble where all evidence seems to point to the sinuses as the portal of entrance of the infection.

Case I.—A. L., male, aged twelve. Referred by Dr. M. R., January 18, 1925.

Nasal discharge since infancy. Frequent attacks of tonsillitis; measles. No other illness, no rheumatism. At age of nine had tonsils removed. Ever since the nose had been discharging more profusely than before the operation. About four years ago was told by a physician that he had heart trouble. During the past two years had been attending a cardiac clinic in a well known hospital in this city. His appetite was poor and he became cyanosed and dyspneic on the slightest exertion.

The following report came with the patient from his physician. Patient pale, anemic, underweight and undernourished, cyanosed and dyspneic. Heart was enlarged both to right and left beyond nipple line. Loud systolic murmur at apex transmitted to left along fifth interspace to axilla. Spleen and liver palpable. Lungs had scattered mucus râles at both bases posteriorly. Slight edema of both legs.

Both nares filled to capacity with thick pus, which on removal by suction showed a roomy nares with marked postnasal atrophy. Mucous membrane pale and atrophic. Throat showed scars at site of tonsils; marked postnasal drip of thick pus. A slight retraction of both drums. X ray examination of the nasal sinuses showed marked clouding of both maxillary antra, also poor illumination of the ethmoid sinus on both sides.

A diagnosis of chronic suppuration of the maxillary sinuses was made and the following course of treatment outlined.

On January 25, 1925, both maxillary antra were punctured and antroscoped. Both sinuses were found about a third filled with purulent secretion and mucosa diffusely studded with small and large polypi. Antra were then irrigated.

After three weeks of treatment the patient's general condition improved. Cyanosis and dyspnea completely disappeared as well as the edema of the legs and ankles. The nasal discharge was very scant. The patient then disappeared for eight months and returned because of a fresh cold in the nose and nasal discharge for the past two weeks, otherwise there was no other complaint. Treatments were resumed and continued for six weeks with the result that the sinuses appeared to have cleared up completely. His general condition was improved to the ex-

tent that he was able to resume school and attend it regularly as he had never done before. His heart condition was reported as markedly improved and well compensated. Liver and spleen not palpable. Edema absent, and exertion was followed by slight dyspnea not sufficient to disturb patient. At this period and against my advice the treatments were again discontinued, for the reason that the parents thought that their child was entirely well and needed no further treatment.

CASE II.—C. F., male, aged thirty-one, married, salesman. Referred by Dr. L. J. F., August 4, 1925.

Had very frequent colds in the nose. Had been confined in bed in a hospital for several weeks suffering with pains in small joints of hands and feet as well as elbows and knees. Tonsils were removed with some slight improvement. Suffered from marked shortness of breath, precordial pain and distress on slight exertion and frequent attacks of cardiac palpitation.

Physical examination reported by his physician was as follows: Patient was poorly nourished. Appeared dyspneic on slight exertion. Heart was enlarged to right, also to left going two fingers' breadth to left of nipple line. Loud systolic murmur at the apex and transmitted to the left. Second aortic accentuated. Lungs negative.

Septum deviated to the right. Roomy and atrophic left nares. Latter filled with small amount of pus. Tonsils had been removed. Ears were negative. X ray plates of sinuses taken by the physician referring this patient showed absence of illumination of the left antrum, with uniform clouding suggestive of fluid in it; also some clouding of the left ethmoids.

A diagnosis of empyema of the left antrum of Highmore was made.

On August 30th the left antrum was punctured and found to be completely filled with pus, which on being washed out revealed on antroscopic examination the mucosa studded diffusely with polypi. A large opening was then made in the nasoantral wall by enlarging the puncture made. The antrum was treated daily by irrigations and instillations of argyrol and silver nitrate solutions.

About two weeks following the operation the patient was completely free from all pains in the joints and other discomforts and complaints. He resumed his work as salesman in a haberdashery, and did his work which he had not been able to do in the past four months. His precordial pain and discomfort, palpitation with dyspnea and cyanosis on slight exertion almost disappeared. The antrum was dry and mucous lining showed marked improvement. Treatments were continued until September 30th and the patient discharged. Patient was referred back to his family physician with instructions to continue treating his cardiac condition which was reported as markedly improved. Patient was again seen November 22, 1925, was found doing well, with no recurrence of his previous complaints.

CASE III.—A. H., twenty-five years old, single, post office clerk, referred to me by Dr. H. G. K., June 14, 1923.

Patient came with the following note from his physician: "Mr. H. is suffering with a mitral regurgitation and enlargement of the heart; subject to constant colds in the nose and tonsillitis. Nasal discharge is profuse and constant and is very disturbing to the patient. Complains of pains in the chest and precordium. Gets tired and dyspneic on slight exertion."

Nose filled with thick purulent secretion. Septum S shaped deflection. Throat showed hypertrophied diseased tonsils. X ray of sinuses showed very intensely cloudy antra, with poor illumination of the ethmoids.

Chronic suppuration of antra and ethmoids with discharging empyema of the antra was the diagnosis. I advised a preliminary tonsillectomy with subsequent opening and drainage of the antra and ethmoids. The patient did not return for treatment until two years later, June 7, 1925. He gave the additional history of having since been married and had one child. His health was poor, he was having constant nasal colds and attacks of grippe, had not been able to work regularly for months. Had had no sore throat at all. His rhinoscopic picture remained the same.

Patient would not consent to a tonsillectomy, on the ground that he was both afraid to have it done and that he did not think it was at all necessary. On May 8th I punctured both antra. The left antrum was filled with pus and mucosa diffusely studded with small and large polypi. The right antrum had but little pus, with moderate polypoid changes in the mucosa.

There was a marked improvement within three weeks after the operation, both in the general condition and the suppuration of the sinuses opened. At the last examination on October 3, 1925, the patient had been working regularly during the past two months. The nose was dry and free from acute colds and profuse discharge. Chest pains and discomfort about the heart had completely disappeared. He became dyspneic only on marked exertion. Had gained in weight and strength.

CONCLUSIONS

1. From a study of the foregoing three cases the conclusion is reached that the nasal sinuses do play an important rôle in cardiac pathology, particularly when definite pathology (in the nasal sinuses) can be demonstrated.

2. The examination of a patient suffering from heart trouble should not be considered complete without an x ray examination of the nasal sinuses, and an interpretation of the latter made by a competent rhinologist.

3. An x ray plate showing a clouding of a sinus always means pathology in that sinus.

4. Every suspected sinus should be explored by puncture, antroscoped and subsequently drained and airated, if found to be pathological.

5. The operative procedure to be employed in cardiacs should be most conservative.

Historical Medicine

Homeric Surgery and Anatomy

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

In his work on *Medicine in Homer,* Daremberg has written two distinct chapters, one on anatomy and one on surgery. This plan will not be adopted here because we wish to retain the spirit of the text of the great poet. In point of fact Homer was neither an anatomist nor a surgeon; he was a poet who sang the Trojan war. We therefore believe it preferable to survey his poem with special reference to his anatomical and surgical remarks. It will be shown that in certain places he almost gives a true surgical clinic, which, if extracted from the text itself, would certainly lose its value. Naturally the *Iliad* is the richest mine from the medical point of view. In fact we must not forget that this poem in its entirety describes the war of the Trojans and Achaiens and that, consequently, an observer with Homer's wide view would be able to find much surgical and anatomical matter. Therefore we will run through the *Iliad* canto by canto and will conclude the chapter with a few remarks relating to what is found in the Odyssey.

THE ILIAD

Canto I. When Homer speaks of Juno he frequently employs this expression: "Oxeyed Hera," and it may be questioned whether or not the goddess was afflicted with exophthalmic goitre. However, there is a reason which would tend to prove that this diagnosis is somewhat exaggerated, because Juno is a goddess, the wife of Zeus, who, as we shall see later on, she can fascinate and seduce by her charms. Hence it is very probable that her esthetical makeup must have been practically without reproach. An enlarged thyroid gland would not have added to her beauty and it is probable that the poet merely wished to imply that Hera had large and very soft eyes.

Then when Homer describes Vulcan he calls him "Hephaistos limping on both feet." It is very probable that Vulcan had a bilateral congenital dislocation of the hip. The expression "limping on both feet" fairly well represents the waddling of a duck, which always provoked inextinguishable hilarity on the part of the gods when the divine smith walked among them to pour them sweet nectar. For that matter we will later on point out that Hephaistos himself recognizes his deformity, which by the way probably accounted for his conjugal misfortunes.

Canto II. Thersites harangues the Achaiens to incite them to fly from their chiefs, but the brave Ulysses quickly overcomes these warriors on account of his great military valour. This task of Ulysses was certainly easy because Thersites was the most deformed man who came before Ilios. He was crosseyed and limping, his shoulders were so rounded that they touched his thorax, while on his pointed head were only a few scattered hairs. With strabismus, rickets and baldness this unfortunate person could not make a good impression. His gross behavior drew a sharp rebuke from Ulysses, who at the same time struck him on the back and shoulders, causing a bloody tumor to develop on his back. This bloody tumor is evidently a very large ecchymosis or perhaps a serosanguinous collection produced from trauma. The description of this case is quite perfect and, although today the medicolegal aspects would be more complete, the report would nevertheless begin with a summary description as given by Homer, before entering into more detail.

Canto IV. "And the first, Antiloklos killed Ekhepolos Thalysiad, courageous Trojan, one of the bravest who fought at the front. And he struck him over the helmet covered with thick horsehair, and he pierced the forehead, and the bronze point penetrated the back." When Homer says that he struck upon the helmet, he probably implies the area of the head upon which the helmet rests, because the latter would have been sufficiently resistant to turn off the javelin. Then, too, one could not very readily understand how the weapon could have pierced the forehead and skull if the force of the weapon had already been broken by the bronze. However this may be, a better description of a fatal wound of the skull could not have been given, since the Trojan fell like a log during the severe fighting.

Next we have a wound of the thorax. Aias kills Simoeisios by striking him in the region of the right nipple and the bronze point came out through the shoulder. Here we have a perfect anatomical description and we are able to follow the weapon throughout its entire course in the body. This description might even be compared to those given us by the immortal Rabelais who, physician as he was, and unusually well versed in anatomy, relates cases with such detail that they can be considered almost as autopsy reports.

Further on in the Canto it is Ulysses who, wishing to avenge his companion Leukos, strikes the Trojan Demokoon on the temple and the point of bronze comes out through the opposite temple, and he was blinded. It is evident that a god could not recover from such a wound, the temple being one of the dangerous regions of the human body, to which Homer will refer later on.

Afterwards comes the death of Diores Anarxnkeid. The complete description of the poet will be given because it is replete with anatomical and surgical reflections. "And he was struck in the right ankle by a pointed stone and the uneven stone shattered both tendons and the bones (evidently producing a bimalleolar fracture). And Diores fell backwards in the dust, extending his arms towards his companions and hardly breathing. And Peiros ran forward and plunged his javelin near the umbilicus and the intestines became spread upon the earth. And darkness fell upon his eyes. And as Peiros rushed forward the Aitolian Thoas struck him in the thorax with his lance just above the nipple and the bronze passed

through the lung. Then Thoas rushed forward and tore out the fearful javelin and, drawing his sword, he ripped up Diores's belly and killed him." The man had certainly great vital resistance because after a small abdominal wound through which the intestines could escape, it was hardly necessary to give him a *coup de grace* by ripping up the abdomen.

Canto V. The goddess Pallas Athene gave strength and audacity to the Tydeid Diomedes; she even caused inextinguishable fire to issue from his helmet and shield, similar to the autumn star which glitters out of the Okeanos. Thus, when Phygeus threw his long spear at him its point merely grazed the left shoulder of the Tydeid and did not wound him. On the other hand, the weapon of the Tydeid was not useless, for he plunged it into the chest of the warrior between the breasts and threw his adversary down.

Agamemnon also threw the great Odios, the chief of the Alizones, from his chariot, and as he fled Agamemnon plunged his lance into his back between the shoulders and the weapon pierced the thorax.

Moreover the Evaimonid Eurypylos rushed upon the divine Hypsenor, and as he fled he struck his shoulder with his sword and cut off the arm, which fell to the ground heavily and dripping with blood.

It is evident that Homer had no difficulty in describing various types of wounds occurring in all parts of the body. "And Meriones chasing Phereklos struck him in the right buttock and the point of the spear went through the bone and reached the bladder."

Now this wound could not have been the invention of the poet, because the description is anatomically correct, and the same applies to the following case: "And the illustrious Phyleid approaching him, struck the back of his head with his lance and the point came out through the teeth, severing the tongue and the warrior fell to the ground clenching the cold bronze in his teeth." For any writer a blow struck on the back of the head is quite sufficient to stun the man, yet Homer is still more precise and he describes the course taken by the lance coming out through the dental arches.

Homer also knew that when a weapon remained in a wound it would act as a hemostatic and that the blood would not flow until the weapon was withdrawn. This is what happened to Diomedes, wounded by Lykaon. A rapid arrow struck him in the shoulder and when it was withdrawn by Sthmelos the blood spurted forth covering his tunic. This occurrence, however, did not prevent him from getting into his chariot under the protection of Pallas Athene and continuing a single combat with Lykaon. "Then he threw his lance and Athene directed it to the nose, near the eye, and the undaunted bronze passed through the white teeth, severing the end of the tongue, and came out through the chin." In one of the cases already mentioned, the weapon inflicted a wound from behind forwards, but in this case the result is the same because the life of the warrior was involved.

The Tydeid Diomedes continues his exploits and, seeing Aineias running forward to remove Lykaon's corpse, he seized hold of a heavy rock and struck Aineias on the thigh at a point where the femur turns in the cotyloid cavity, and the rough stone, hitting the hip joint, ruptured the two upper muscles and tore the skin. The hero then fell on his knees, because he certainly had a fracture of the upper end of the femur, very probably complicated with a fracture of the pelvis.

What seems to be a less likely thing is that in such a condition Aineias was able to return to the battlefield in a few days in possession of all his strength. It is true, however, that in order to explain this Homer invokes the intervention of the goddess Aphrodite and the god Apollo.

In a single combat between Sarpedon and Tlepolemos, both warriors threw their long lances at the same time; "and Sarpedon struck Tlepolemos in the middle of the neck and the sharp point of the weapon went completely through, and darkness fell upon the eyes of Tlepolemos. But he had pierced Sarpedon's left thigh with his long lance, and its point remained wedged in the bone, and his father the Kronide turned death away from him. And the brave companions of Sarpedon carried him away from the fray. And he groaned, dragging the long oaken lance in his wound, because none of them had dreamt of tearing it from the thigh of the warrior, so that he could get into his chariot, in such haste were they."

Canto VIII. The reader is undoubtedly familiar with the famous wound of the cerebellum which Paris inflicted upon Nestor's horse. He pierced the top of the animal's head with an arrow, a vital spot, there where the upper part of the mane turns over. The weapon, having penetrated the brain, the animal was seized with pain and rolling on the ground, terrified the other horses.

Another vital spot is the region where the clavicle divides the neck from the chest, on account of the presence of large bloodvessels and nerves. It was thus that Hector struck Teukros on the shoulder with a hard stone and he fell to his knees, letting his bow fall from his hand because his wrist was also crushed.

Canto X. Homer describes an instance of decapitation. The traitor, Delon, offers his services to Ulysses and as a reply the latter suddenly struck him with his sword in the middle of the throat, severing both muscles (the sternocleidomastoid muscles). The Trojan spoke when his head fell into the dust, which unquestionably is a peculiar phenomenon.

Canto XI. "In Hector's presence, Diomedes threw his long lance which turned not away from its target, for the blow fell upon the top of the Priamid's helmet. The bronze point could not penetrate and rebounded; thus the helmet of triple bronze, given to the Priamid by Phoebus Apollo, saved him. But the warrior at once recoiled and then, entering into the crowd, he fell upon his knees, supporting himself with his strong hand, and darkness fell upon his eyes." This is undoubtedly a case of cerebral concussion. Hector's helmet protected him from the weapon, but the impact was so strong that it caused concussion of the brain and he lost consciousness.

Agamemnon was more seriously wounded by the warrior Koon, who struck him with a lance in the middle of the arm below the elbow, and the point of the brilliant weapon went through the arm. Agamemnon did not at first feel his wound, a common occurrence on the battle field, and continued to fight as long as the blood flowed from the wound, but as

soon as it became dry, the blood having been staunched, acute pain developed, and conquered his strength so that he was obliged to return to his ship. The same phenomenon is observed in Diomedes, wounded by Paris, who sent an arrow into the right foot of his adversary. The arrow went through the foot into the ground and it was only when Ulysses drew out the weapon that Diomedes experienced such sharp pain that he also was obliged to return to his ship.

Homer also describes a wound of the liver and shows very clearly that he knew that this gland is situated under the diaphragm. Eurypylos pierced the Phausiad Apisaon, the prince of people, in the liver, under the diaphragm, and killed him.

Canto XIII. In this canto Homer gives an excellent description of the twitchings occurring when a mortal wound has been inflicted. Idomeneus struck Asios in the throat, under the chin, and the weapon pierced the neck. The warrior fell to the ground and remained extended in front of his horses and chariot, grinding his teeth and plucking at the blood-stained dust. He also was the recipient of a famous *coup de grace* in the middle of his belly, given him by Antilokhos.

The liver of the Hippasid Hypsenor was also considerably damaged by Idomeneus. The blow was so violent that his knees gave way. A little further on Homer shows that the point of a lance lodged in the heart does not cause the organ immediately to stop beating, because the weapon oscillated with the cardiac contractions.

Idomeneus continues his exploits by perforating the intestines of Oinomaos, who fell "clutching the earth with his hands." The latter expression is very probably used in order to show that the body of the warrior fell forward; the truth of this is still further demonstrated by another Trojan who fell backward on the dust after having received a wound which severed the vein which "running along the back reaches the neck." The question now arises what vein Homer refers to. It is not likely that it is the azygos which naturally was unknown to him, no matter how great his great anatomical knowledge may have been. Then, too, severing this vein would not result in such sudden death as that described by the poet. Hence one may conclude that it was the inferior vena cava which was involved.

Meriones, pursuing Adamas who was fleeing, pierced his body between the umbilicus and the genital organs, a region where a wound is fatal for men, so Homer informs us. There is here evidently a mistake in the poet's topographical anatomy. It is probable that the very dangerous region referred to must be that of the celiac plexus and this is situated quite a little above the umbilicus. This is not a sufficient reason, however, to doubt the real anatomical knowledge of the poet; it should not be forgotten that he merely observed and that certainly he had never dissected.

Next it is Helenos who was struck by an arrow from the bow Menelas. The wounded warrior did not waste time in withdrawing the weapon and entered the fray with the arrow hanging from the hand. In this case a woollen sling was used as a dressing. Menelas did not remain idle for meeting Peisandros, he struck him over the forehead above the nose and the bones creaked and his bloodstained eyes burst out and fell to his feet in the dust. Such an injury could not be produced by a spear, therefore a little further on Homer states that Menelas had drawn his double bladed sworn, consequently one can readily understand that by a sharp blow he could shatter the frontal bone and that the weapon could penetrate sufficiently deeply to sever the extrinsic muscles of the eyes, the optic nerve, and all other means of contention, hence the eyes could fall from their sockets. In this canto there is also mentioned another instance of perforation of the bladder by a weapon passing through the right coxofemoral joint.

Canto XIV. Homer has noted that one of the frequent complications of blows on the chest is hematemeses and hemoptysis. With a rock Aias struck Hector on the chest above his shield, in the region of the neck. The warrior fell from the blow and when consciousness returned he opened his eyes and vomited black blood, after which he fell back on the ground. This is a case of traumatic hematemesis.

Then comes another instance of decapitation, but this time it is accomplished from behind forwards; Homer knew the sternomastoid muscles as has been shown, and in the present instance he shows his knowledge of the muscles of the neck. It is evident that he also knew that the cervical and dorsal vertebræ were not alike, at least this may be supposed from the following remark: "he was struck over the last vertebra of the neck and both muscles were severed, and his head, his mouth and his nostrils touched the ground before the knees." Here again we find that precision of detail which shows the considerable anatomical knowledge of the poet.

Canto XV. Here we see Hector facing Lykophon and striking him with his sharp spear just above the ear, thus causing the warrior to sink down. In this instance Homer wished to describe shock resulting from a blow over the temporal region, just as a little further on, when he depicts Kleitos stunned by an arrow entering the back of the neck, he shows that he knew that the bulb of the brain was to be found in this region and that as soon as it was injured death was instantaneous.

Homer frequently speaks of javelins piercing the chest near the breast, as happened to the proud Menalippos. It is probable, since he takes the trouble exactly to describe the point of entrance as being near the breast, he wishes to imply a wound of the precardiac region.

Canto XVI. The Phyleid struck Amphiklos low down on the thigh at the point where the muscles are very thick, and the head of the spear tore the nerves. This may be interpreted as a wound of the upper part of the poplital space, but the nerves referred to are the tendons.

Maris, attempting to avenge his brother, Amphiklos, was struck by Thrasymedes who pierced his right shoulder and the point of the weapon by severing all the muscles stripped the bone of all the flesh attached to it.

Aias Oiliad struck Kleoboulos in the neck, but before the weapon penetrated into the throat it cut both carotid arteries, thus giving rise to fatal hemorrhage.

Next Homer gives us a faithful description of fracture of the skull in the following pasage: "Ido-

meneus struck Erymas in the mouth with his spear and the bronze point went into the brain breaking the white bones (the small bones of the base of the skull); all the teeth were loosened and both eyes filled with blood, while blood gushed forth from the mouth and nostrils. And darkness fell upon his eyes." The symptomatology of fracture of the skull is here quite complete.

Canto XX. Achilles split open the head of the Trojan Otrynteid with a stone. He also burst Demoleon's temple, although it was covered by his helmet, but as this is a weak point of the skull the bone was broken and crushed the entire brain. Here is the description having a really striking reality. Achilles pursued Polydores Priamid and struck him in the back at the point where the clasps of gold attached the shoulder belt to the double breast plate. The point of the weapon pierced the body to the umbilicus and the warrior fell to his knees.

What is less true is the tearing out of the liver by a blow of a sword which Homer attributes to Achilles in the person of the Trojan Alastorid.

Other wounds of battle are described in cantos XXII and XXIII but enough has been said to show the great anatomical and surgical knowledge of Homer.

THE ODYSSEY

Anatomy and surgery are practically missing in the *Odyssey* and what little is said of them is merely a repetition of what is found in the *Iliad.* It is certain that Homer considers the hepatic region as very dangerous because the intestine surrounds the liver, and it is for this reason that Ulysses wished to strike the Cyclops with his sword in this region. This adventure gives the poet an opportunity to describe with pathological exactitude the wounds received by the Cyclops. Ulysses, after having heated his olivewood javelin in the glowing ashes, pushed it into the eye of the Cyclops and then turned it round as a shipwright bores holes in the wood with his augur. . . . And the blood gushed out from the eye and the vapor of the firey pupil burnt his eyelids and eyebrows."

There is another instance of wound of the liver occurring to Eurymakhos from a javelin thrown by Ulysses but in such a direction that the weapon pierced the warrior's chest near the breast and continuing onwards became wedged in the liver.

As a conclusion it may be said that the descriptions of wounds given by Homer prove that the topographical anatomy of the human body was no secret to the ancient Greeks.

Contributors to the Science of Medicine

John Locke

John Locke is put down in a medical biography published in 1799 as a very celebrated philosopher and one of the greatest men England ever produced. He was these and an authority on certain branches of medicine as well. He wrote a work on the rearing of children which may be read with advantage in these days.

John Locke was descended from what was termed then a "genteel family" in Somersetshire, once possessed of a handsome estate, but much impaired when it came into his hands from his father who was bred to the law, and who followed it, till the breaking out of the civil war under Charles I, when he entered into the service of the parliamentary party. William Harvey was a staunch royalist and Thomas Sydenham a follower of Cromwell.

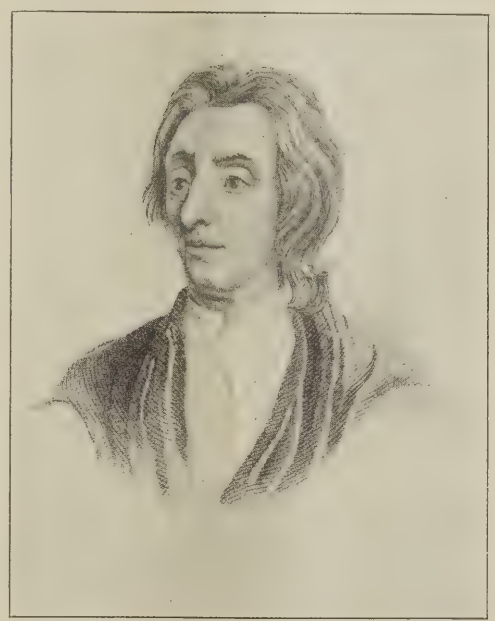
John Locke was born near Bristol in 1632 and educated at Westminster School whence he went to Christ Church College, Oxford, in 1651, where he excelled in polite literature. He took his degrees in arts in 1655 and 1658 and then took up medicine, went through the usual courses preparatory to practice, and commenced practice in Oxford. But being of delicate constitution, the work proved too hard and he accepted the offer made to him of secretary to Sir William Swann, envoy to the elector of Brandenburg, the Hohenzollern ancestor of the ex-Kaiser.

After a stay of a year in Germany he returned to Oxford and was continuing his medical studies when he became acquainted with Lord Ashley whom he treated successfully and who made him his house physician. However, he did not confine himself to medicine but applied himself to the study of politics, ecclesiastical and civil. About the year 1669 he attended the Countess of Northumberland into France but returned to England in 1670. On his return he lived as before with Lord Ashley, then Chancellor of the Exchequer, who, jointly with some other lords, having obtained a grant of the State of Carolina, employed Locke to draw up the fundamental constitutions of that state. Locke still retained his student's place at Christ Church College and went to reside occasionally at Oxford for the sake of study as well as for change of air. He had conceived an early aversion to the teaching and the methods of Aristotle and began to collect material for his own great work, *Essay on Human Understanding.* In the meantime his patron, Lord Ashley, who had been created Earl of Shaftesbury and made Lord Chancellor in the following year, appointed him to a lucrative post. He held this place until 1673 when his master being deprived of the Lord Chancellorship, Locke fell into disgrace also.

In the beginning of 1674 he took his bachelor's degree in physic at Oxford, and in the following summer went to Montpellier, being in the quaint phraseology in vogue then "inclinable to a consumption." He continued abroad until 1679 and occupied himself partly in the preparation of his essay and partly with his profession.

Locke seems to have combined philosophy with

medicine to his own satisfaction and to the benefit of humanity. He is said to have been esteemed greatly by the faculty of medicine and especially by his friend, Sydenham, the most celebrated practitioner of the day and whose method of practice he approved and followed. He wrote a Latin copy of verses, which were prefixed to the *Observationes Medicæ,* which Sydenham published in 1676 and in 1677 having left Montpellier, he wrote from Paris to Dr. Mapletoft, another renowned English physician, professor at Gresham College, intimating, that in case of a vacancy by that friend's marriage, he should be glad to succeed him. He remained in France until he was sent for by the Earl of Shaftesbury, but who again being disgraced and impeached shortly afterwards succeeded in escaping to Holland to avoid a prosecution for high treason and was followed by Locke. After the death of the Earl he found it necessary for his own safety to remain abroad, as he was suspected of being a confederate. So strong was this suspicion that he was removed from his student's place at Christ Church, Oxford, in 1684, by a special order of King Charles II. Locke thought this action so malicious that when he returned to England, after the revolution by which James II was deprived of the throne, he put in his claim to the studentship, but the claim being rejected, he declined the offer of being admitted as a supernumerary student. It was in the same spirit, when he was offered a pardon from Charles II, by William Penn, the famous Quaker, who had known him at college, he refused it alleging that being guilty of no crime he had no occasion for a pardon. In May of 1685 the English envoy at the Hague demanded that he be delivered up by the States General on suspicion of being concerned in the Duke of Monmouth's invasion. Because of this he lay concealed for nearly twelve months, during which period he spent his time in writing books and chiefly his *Essay on Human Understanding.*



JOHN LOCKE

In 1687 he formed a weekly assembly at Amsterdam with Limborch, Leclerc and others, for holding conferences on subjects of learning, and at about the end of the year finished his great work the "Essay" on which he had spent more than nine years. At the same time he made an abridgement of it which was translated into French by Leclerc, and published in his *Bibliotheque Universelle* in 1688. This abridgement was apparently sent out for the purpose of feeling the pulse of the public and it being found to be appreciated by a large number of persons, Locke published the complete work soon after his arrival in England in the fleet that convoyed the Princess of Orange to her husband in February, 1689.

As he was regarded as a sufferer for revolutionary principles, he might have easily have obtained a lucrative post, but contented himself with that of Commissioner of Appeals, worth £200 a year. About the same time he was offered posts in the public, now termed diplomatic service, and he was given the choice of being envoy at the court of the Emperor of Austria, of the Elector of Brandenburg, or at any other which he thought was best suited to his health. However, he declined all these offers on account of the precarious state of his health and went to live in the house of some friends in Essex not far from London. Here his health improved considerably and his time was taken up chiefly in writing on various subjects. He was made a commissioner of trade and plantations in 1695. In 1700 he resigned his seat at the board of trade and lived in the country for the remainder of his life. He died on October 28, 1704, in the seventy-third year of his age.

The writings of Locke cover a wide range of topics and have been published many times, the most complete edition appearing in 1823. His celebrity as a philosopher, however, rests mainly upon his two treatises, *Essay on Human Understanding* and the shorter work entitled *Conduct of the Understanding.* The former of these works was commenced as early as 1670, and was finished in 1687. It was followed in the next few years by the *Letters on Toleration,* the *Treatises on Government, Thoughts on Education,* and several minor essays in vindication of opinions advanced in his larger works.

While Locke was greater as a philosopher than a physician, he was accounted one of the first physicians of his day. As a philosopher he is placed on a plane with Bacon and Newton, and it is on his works in philosophy that his fame rests. There is probably no writer on philosophy who has produced such a broad and solid effect on the mind of the English people. Few have turned their attention to metaphysical inquiries without reading his *Essay on Human Understanding.* D'Alembert says that Locke created the science of metaphysics in somewhat the same way as Newton created that of physics; and his inquiries into the origin, development, and combination of our thoughts justly entitle him to be called the founder of psychology in England.

History of Diabetes.—In a book entitled *Facts and Opinions Concerning Diabetes* John Latham published in 1808 his experiences with diabetes. He distinguished two forms of diabetes, saccharine and serous, and recognized the difference between diabetes mellitus and diabetes insipidus. He may thus be considered as one of the founders of our knowledge of diabetes. In his book he gives an excellent history of diabetes. (*English Physicians of the Past.*)

ORAL SEPSIS AND HEART DISEASE

What is the main cause of heart disease, now the most deadly and invaliding disease of civilization? The answer of the majority of medical men to this question will be probably rheumatism in all its forms and acute rheumatism in particular. In childhood acute rheumatism and scarlet fever play prominent rôles, and in all cases of what is known as toxic heart the condition of the mouth is a factor which must be always considered.

In a second edition of Sir Kenneth Goadby's book, *Diseases of the Gums and Oral Mucous Membrane,* published by Oxford University Press, the question of poisoned heart is dealt with at some length by the author in collaboration with Dr. Strickland Goodall, of London, the well known heart specialist.

In reference to poisoned heart, Sir James Mackenzie in his *Diseases of the Heart* has this to say: "The muscle of the heart may be impaired by agents which infect it in the manner of a poison without producing structural changes, unless the poison is long continued, when by its persistent action it may lead to structural changes." As for treatment, Sir James says, "The appropriate treatment is to get rid of the poison. Simple as this proposition seems, yet it is wonderful to find how often it is neglected, or, if not neglected, how attempts are made to cure the heart as if it were something apart from the intoxication."

Goadby and Goodall have investigated numerous cases of socalled poisoned heart in which the origin of the poison was traced to diseases of the gums and jaws. Goodall points out that the term poisoned heart or toxic heart indicates neuromuscular impairment as distinguished from primary defects of the heart mechanism, although, of course, this latter condition may arise as a complication or a sequela. The actual poison affecting the heart may be one of the definite alkaloids such as nicotine, or a combination of poisons such as digitalis, this drug producing poisoning without gross structural alteration. Diphtheria toxin is another well defined poison whose action upon the heart muscle is acknowledged. The poisons of bacillary dysentery and again of malaria are of a fairly well defined nature, and are known to produce toxic effects upon the heart muscle. Among the more indefinite poisons are those arising from certain diseases, as, for instance, influenza, acute and chronic rheumatism. Such a list does not exhaust the poisons which may affect the heart muscle, and electrocardiographic investigation has shown that the action of poisons upon the heart appears to be of a twofold nature; just as there are group agglutinins and specific agglutinins for bacteria, there is what may be called a group action and a specific action leading to progressive alteration in the irritability, contractility, conductivity, or tonicity of the myocardium.

Goodall shows a series of electrocardiograms illustrative of the profound action of various poisons upon the heart muscle. For example, the effect of large doses of digitalis producing coupled beats. Impaired conduction and increased irritability following diphtheria. Increased irritability of a heart subject to the attacks of paroxysmal tachycardia following influenza. Again influenza may produce a totally different effect, as seriously impaired conduction producing heart block. Poisoned hearts are common after influenza. Attention is drawn to the fact that in acute rheumatism evidence for the streptococcal origin of the poison is great. Moreover, in addition to the general poison effect there is some evidence of specific action. Thus in streptococcal infections, pericarditis may be a complication and may also supervene in certain other infections by the pyogenic cocci; whereas in diphtheria with its microbic cause strictly localized pericarditis is as yet undescribed. A poisoned heart may be a complication of chronic rheumatoid arthritis, admittedly associated with mouth infections. Goodall's series of electrocardiograms of persons suffering from oral sepsis demonstrate in a most illuminating manner that the effect of poisons of various grades is to induce changes of a profound nature in the functions of the cardiac muscle.

In addition, in their early stages the alterations in conductivity, irritability, contractility or tonicity may exist without obvious clinical or objective symptoms, but may be detected by appropriate methods.

There is, of course, no doubt that oral sepsis is often intimately associated with that condition known as "poisoned heart" and is a factor in its causation of the first importance. As to whether septic conditions of the mouth are secondary to those of the gastrointestinal tract is still a moot point. Many believe that the origin of a great deal of oral sepsis is gastrointestinal disorders and intestinal stasis in particular. However, it is certain that oral sepsis aggravates bad gastrointestinal conditions and vice versa. A vicious circle is formed which can be broken only by rational means. Sir James Mackenzie's advice to get rid of the poison and not to treat the heart only is manifestly sound. Oral sepsis should be remedied as far as possible and the gastro-

intestinal and urinary tracts should be cleansed to the utmost. Elimination and excretion should be rendered free. It is likely that poisoned heart is more common than is generally believed, although the part that rheumatism is playing in producing heart disease is beginning to be recognized as one of the greatest menaces of modern life. By preventing poisoned heart from developing, much mortality, sickness and trouble of many varieties will be also prevented.

THE TREATMENT OF CHRONIC HEART FAILURE

The great man who died a short time ago, Sir James Mackenzie, greatly improved if he did not revolutionize diagnosis of heart disease and abnormal conditions, and in recent years this improved knowledge has aided immensely in bettering treatment. It is obvious that if views as to the causation of heart disease are lacking in intelligent comprehension, treatment fails frequently. But knowledge of the heart has so increased that its treatment is now based largely on scientific principles. In the *Canadian Medical Association Journal* there was published recently an address delivered before the postgraduate class at Dalhousie University, by Dr. Robert Dawson Rudolf, of Toronto, on September 8, 1924.

Dr. Rudolf begins by pointing out that it is scarcely necessary nowadays to say that heart failure means failure of the myocardium and people do not die of mitral disease or of aortic regurgitation as was believed up to a comparatively recent date. It is only in so far as lesions of these parts hamper the action of the muscle that they have any significance. Moreover, heart failure signifies failure of the ventricles, for as long as these are working sufficiently there is no failure, even although the auricles may have struck work completely and are in a state of fibrillation.

Heart failure is by no means synonymous with auricular fibrillation, although the two are associated quite frequently. Failure may occur in a regular heart and may be absent in an irregular one. As a rule, a failing heart is a fast one, but this is not the case always.

It is extremely difficult to differentiate between true and false cardiorenal disease, but either condition can be judged often with a fair degree of accuracy by clinical observation and by observing and testing the urine. In cases of cardiac failure rest is indicated, but rest in proportion to the degree of failure. In very slight cases of cardiac insufficiency carefully regulated gentle exercise is often of value in improving the tone of the myocardium. Rudolf insists that in all cases of heart failure the bowels should be kept opened freely; in his opinion this object is gained best by the daily use of sufficient amounts of concentrated magnesium sulphate solution. In severe cases little food should be given and in patients who exhibit much toxemia the Karrell diet is recommended.

When the digestion is extremely poor, Rudolf advocates the employment of glucose and alcohol. Neither requires any digestion and when absorbed the caloric needs of the sufferer are supplied to a large extent. When alcohol is used thus as a food it should be given in small amounts frequently. It is stated that often rest and perfect dieting are sufficient to restore some of the reserve power of the heart, but usually digitalis is indicated and stress is laid upon the point that it gives marvellous results when properly administered in suitable cases.

Rudolf does not wholly agree with Dr. G. A. Sutherland, *Lancet,* December 8, 1923, that all the good effects of digitalis are due to the slowing of the ventricular rate. There are many with whom Rudolf agrees, who believe that although the slowing from the heart block is of very great importance, and probably is the chief cause of the good effects in these cases of auricular fibrillation, there is much evidence of a direct stimulating action on the heart muscle. According to Rudolf, always use digitalis when drug therapy is indicated in cases of heart failure, except when it upsets the stomach and when coupled beats, cerebral disturbance, and more or less stoppage of the urinary secretion are present.

Sometimes a diuretic is necessary, and Rudolf recommends what in his opinion is the most effective. He, however, places his faith in digitalis and holds that although quinidin may be of value in cases of auricular fibrillation, when the case is complicated with heart failure, digitalis still maintains its position as the remedy par excellence for such failure.

These views are most instructive and very valuable in spite of the fact that several authorities contend that in the vast majority of cases auricular fibrillation is indicative of some myocardial change. Nowadays, medical views on the causation of heart disease are that it is largely brought about by acute rheumatism, especially in childhood, and that if acute rheumatism in childhood could be prevented that heart disease would be much less frequent. Careful diet and living generally, paying particular attention to the excretion and elimination of toxic material by the gastrointestinal and urinary tracts, will no doubt prevent the occurrence of much rheumatism, but in the meantime we have to consider the treatment of organic heart disease, which in all civilized countries is almost the most frequent cause of death and invalidism.

THE HISTORY OF MEDICINE AND NURSING

The history of medicine, in which nursing may be included, is fascinating and at the same time instructive and in a sense not conducive to a too great conceit in present day knowledge. Of course, medicine has had its rises and falls. A high state of culture, written records show, existed in Egypt 9000 B.C., which seems to have reached its apex between 5000 and 2000 B.C. In this and in Babylonia and Assyria, Armenia, Palestine, Persia, India, Ceylon, China, Mexico, Peru and somewhat later Japan, Crete, Greece and Etruria, the view held by primitive man, as the North American Indian and African, that disease was a form of demoniacal possession which must be expelled by blows, had given way to the conception of the priest physician who ministered to both physical and mental needs of patients.

Later these offices were separated and discharged by the priest who performed the religious offices, while the actual treatment of disease was carried out by men who corresponded closely with present day physicians. In Egypt, indeed, were the learned and cultured men of old times and it was from the land of the Nile that Greece procured her medical knowledge which in turn she handed on to Rome. Egypt had great medical libraries and the oldest medical book known is the Egyptian *Ebers Papyrus*. It contains Egyptian medical records written between 4688 B.C. and 1560 B.C., which form an encyclopedia of disease. Little is said of nursing and hospitals in the history of Egypt.

It may be noted that in ancient India nursing was developed to a high degree and the old Indian practitioners studied and practised the prevention of disease more than its treatment. In both India and Ceylon there were hospitals for the sick poor in very early times. Civilization is supposed to have spread from Asia to Greece in or about 3500 B.C. The early Greeks were a hardy, seafaring, clever race of great individuality and originality, which made them later the leaders of the world in art and literature and to some extent in medicine. The Greeks, however, were largely indebted to the Egyptians for their medical knowledge, as well as for other knowledge, and it is from the Egyptians that medical knowledge had its origin. In the times of Homer Greek surgery was more highly developed than medicine, probably on account of the wars which were being waged continually. It must be borne in mind that the Egyptian surgeons were skilful, as has been proved by the examination of mummies on whom many of the difficult operations of modern surgery were found to have been performed. Hippocrates lived in the marvelous fifth century before Christ, the Golden Age of Greece, in which there lived in one country at one time perhaps the greatest philosophers, dramatists, sculptors, poets, writers and statesmen the world has ever known. Hippocrates was the greatest physician and he laid the foundations of modern medicine. After the fall of Corinth Greek medicine migrated to Rome, as it must be remembered that medicine in Rome was almost entirely carried on by Greeks. The last great Greek physician in Rome was Galen, the father of experimental medicine.

In the early Christian times nursing rose to a fairly high standard. It was carried on chiefly by the Deaconess order. The first deaconess was Phebe of Cenchrea A.D. 60, who was sent to Rome by St. Paul to care for the sick there. This order spread rapidly, especially in the Eastern Church, and a form of district nursing was established, which of course is still being carried on. Also Diakonia sprang up everywhere for the care of the sick managed by the order and were the historical forerunners of the modern hospital. In the early church there were many other women workers among the sick outside the Deaconess Order. At this time monasteries and nunneries were founded in which men and women withdrew from the world under vows of chastity and gave up their lives to service and kept the lamp of literature, art and medicine burning. Rich and poor united in organizing hospitals and other charitable institutions dedicating themselves to the service of religion and the sick poor. These beautiful monastic hospitals of the early Middle Ages did splendid work. Up to the eighteenth and early part of the nineteenth century these monastic institutions held sway, when new conditions demanded new forms of social adjustment and the modern hospital system arose to displace them.

Among the celebrated nurses of history the name of Jeanne Mance comes readily to the mind of Americans because she established the second hospital on this continent under most romantic circumstances. Jeanne Mance came from France with Maisonneuve's expedition to found Montreal. The members of the expedition were impelled by religious fervor and inspired by a vision to found a colony on the island now known as Montreal in order to evangelize the Indians. Jeanne Mance joined the expedition with the purpose of founding a hospital. This purpose was fulfilled shortly after the landing of Maisonneuve and the first Hôtel Dieu was built in Montreal in 1642. Jeanne Mance had never taken vows except those of perpetual chastity and after managing the hospital for eleven years returned to France and obtained the services of the hospital nuns of St. Joseph de la Fèche whom she brought back with her to Montreal and placed the control of the Hôtel Dieu in their hands. To Florence Nightingale was mainly due the foundation of the modern nursing system.

Bulfinch Building

The Massachusetts General Hospital

An Historical Sketch

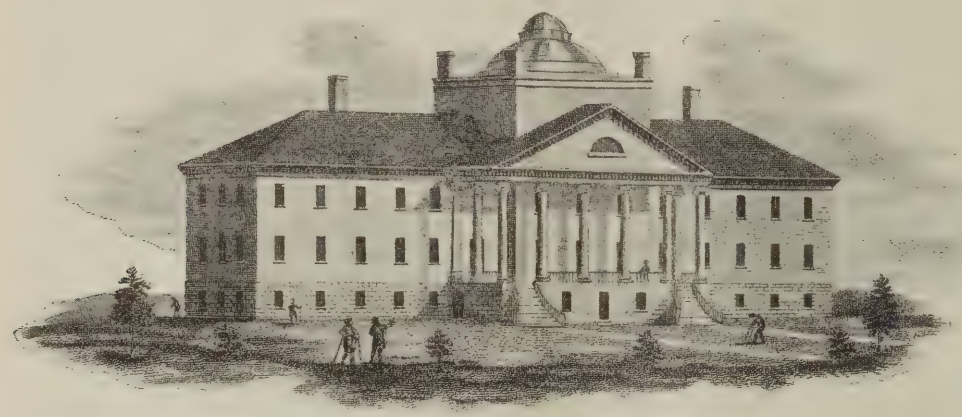
GRACE WHITING MYERS, Librarian Emeritus, Treadwell Library

Boston, Mass.

Under date of May, 1810, a letter was written by the professors of Harvard University to the Overseers of the Town of Boston, requesting their consideration of the question of allowing professors or lecturers to "attend their pupils to the patients in the Almshouse of Boston, for the purpose of remarking on the nature of the cases, and pointing out to them the best methods of treatment and mode of care which their own observations and experience might enable them to suggest. The subscribers have no regard to any form of compensation for any service they might afford, but would be willing that the physicians of the house should receive the usual emolument of the appointment, and would afford him every aid and advantage which it is in their power to bestow as consulting physicians, without fee or reward. . . . If the Overseers think proper to adopt the measure suggested, it would be a means of removing the necessity which students are now under of remaining ignorant of the most important part of their profession, or going to Philadelphia or New York for the sake of attending to the practical part—to attend the hospitals and infirmaries—and thus have the satisfaction of saving a multitude of lives to the Commonwealth by (providing) better measures for qualifying the existing generation of physicians to cure disease than what are, or can be, at present enjoyed. And all without the least disadvantage to the poor who would be treated with more care and attention than can happen in the ordinary routine of medical attendance." In July, 1810, a reply was received acceding to the request for the remainder of the current year. At that time the Pennsylvania Hospital in Philadelphia and the New York Hospital in New York City were the only general hospitals in the country. At a meeting of the above mentioned professors of Harvard University, held on October 20, 1810, it was voted: "That the patients in the Almshouse be divided into two classes, medical and surgical. That Dr. J. C. Warren take charge of the surgical patients. That Dr. (James) Jackson take charge of the medical patients for three months from November 1, 1810, and for one month longer if circumstances required. That House Pupils shall be admitted to attend the Almshouse for the sum of $50 for the year."

Nowhere in New England was there a hospital. The Boston Almshouse was the only refuge in that city for the sick poor and for the insane. The conditions surrounding the latter were deplorable, for

they were literally treated as if "possessed of devils," and not to be approached without some means of self-defense. The Pennsylvania Hospital maintained a department for the care of the insane, and the Bloomingdale Hospital connected with the New York Hospital had been opened the previous year. One other, the State Hospital at Williamsburg, Virginia, completed the list of institutions of this nature.



Original Building

It happened that in November, 1807, a certain Reverend John Bartlett became chaplain of the Boston Almshouse, and he was much distressed by these conditions surrounding the mentally ill. In the early spring of 1810, a particularly grievous case of insanity was brought in, and the chaplain determined to seek some means for more humane care. So he called together a group of representative citizens, including Dr. Warren and Dr. Jackson, already mentioned, and[1] Mr. McLean for whom the McLean Asylum at Somerville, Massachusetts, was later named. Other meetings followed this one, and it was decided to start a subscription list for the establishment of a hospital for the care of the insane, and first subscriptions were for this object; but shortly afterwards it was deemed expedient to unite with it the establishment of a hospital for the sick.

A circular letter was accordingly issued by Dr. James Jackson and Dr. John C. Warren in August, 1810, inviting subscriptions "for a hospital for the reception of lunatics and other sick persons." The letter closed with the following words: "Hospitals and infirmaries are found in all the Christian cities of the Old World; and our large cities in the Middle States have institutions of this sort, which do great honor to the liberality and benevolence of their founders. We flatter ourselves that in this respect, as in all others, Boston may ere long assert her claim to equal praise."

On February 25, 1811, the charter was obtained from the Legislature, incorporating fifty-six of the "most distinguished inhabitants of the various towns of the Commonwealth, by the name of the Massachusetts General Hospital." The first meeting of the Corporation was held April 23rd of the same year. Trustees were first chosen February 2, 1813. "A common seal was ordered to be prepared; and on November 30, 1817, Colonel Joseph May, one of the trustees, laid it before the Board—the device being an Indian with a bow in one hand, and an arrow in the other; and on his right, a star, being encircled with the inscription 'Massachusetts General Hospital'; and it was accepted accordingly."

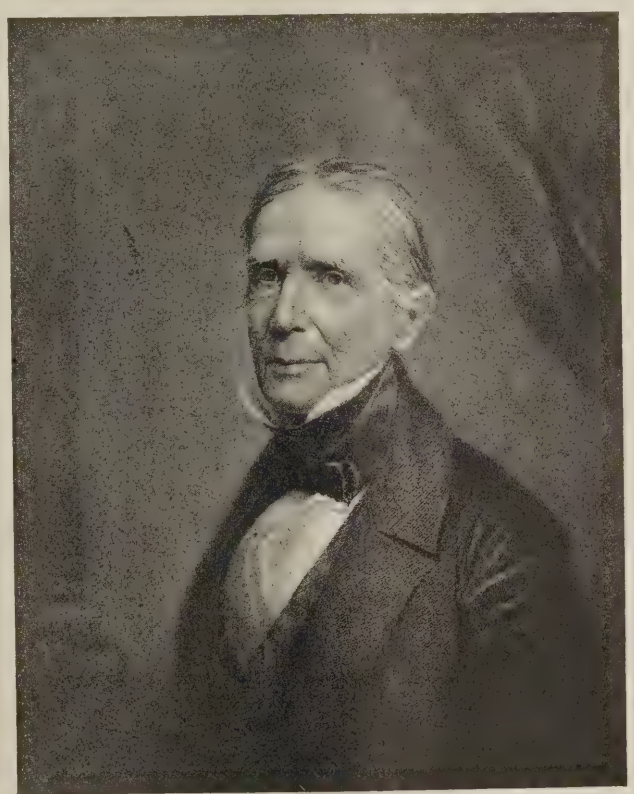
At the time of the granting of the charter the Governor, Lieutenant-Governor, President of the Senate, Speaker of the House, and the Chaplains of both Houses, were constituted a board of visitors. A grant was made of the Province House estate, socalled, with authority to sell the same and use the proceeds at pleasure, provided that within five years an additional sum of $100,000 should be obtained. A further term of five years was later allowed. Province House had an interesting history. It was built in 1679 on the main business street of the town, and in 1716 was purchased from its owner by the Provincial Legislature for the residence of the Royal Governors, and was used as such until the Revolution. After the separation of the colonies from England it became "Government House," and was held by the State until its presentation to the Massachusetts General Hospital. It constituted the first gift to the hospital. Plans were made to remodel the house for a hospital and asylum, but this was found to be impracticable. In 1817 the property was leased for a term of ninety-nine years, the lease expiring ten years ago. The house has now been torn down to make way for city improvements, and during its demolishing some interesting secret passages were disclosed, doubtless used during the days of the Revolution.

Phillips House

[1] In 1832, Mr. McLean left the sum of $25,000 to the Corporation, and named it as his residuary legatee. Eventually the Corporation received nearly $120,000 from the McLean estate.

In 1816 land was purchased in Somerville for the erection of a hospital for the insane. This was built first, and was opened for the reception of patients in 1818. In 1817 land was bought on Allen Street, Boston, as a site of the Massachusetts General Hospital. By a resolution passed by the Legislature, it was provided that stone for the erection of the building should be hammered and fitted for use by the convicts in the State Prison. Several plans for the hospital were received, and referred to a committee. A prize of $100 had been offered for the best one submitted, and this was won by Charles Bulfinch. This first of the many buildings now occupied by the hospital has always been called the Bulfinch Building (Fig. 2). Its distinguished architect had already planned and built the Massachusetts State House, and had been called to Washington to rebuild the Capitol. The cornerstone of the hospital was laid on July 4, 1818, by the Grand Lodge of Masons, with full masonic ceremony. The building was completed in 1821, and the first patient admitted on September 1st of that year. It was three weeks later before the second patient applied.

Dr. James Jackson and Dr. John C. Warren, the founders, became respectively the first physician and the first surgeon of the hospital. Twenty-two patients had been admitted before January 1, 1822; 121 were cared for during the next twelve months. One hundred years later, the corresponding figure was 6,659. In 1848 additions were made to the two wings of the building, increasing its capacity from 93 beds (the original number) to 140. The first additional building was erected in 1854, and constituted a separate ward "for cases of a foul and dangerous nature to relieve and secure other patients from discomfort and risk."



John C Warren

On October 16, 1846, the first public demonstration of the power of sulphuric ether to create insensibility to pain during surgical operation was made in the amphitheatre of the Bulfinch Building. The patient was Gilbert Abbott; the diagnosis, tumor of the neck. Dr. William T. G. Morton, at his own request, was permitted by the operating surgeon, Dr. John C. Warren, to administer the ether in accordance with his recent discovery. The experiment was a complete success the patient declaring that he had "felt no pain." A new era in medicine began with this event, and the old operating theatre in the dome of the building—preserved in its original shape—has long been a Mecca for medical pilgrims. Years later, in 1908, through the efforts of Dr. J. Collins Warren, grandson of the long ago famous surgeon, the annual observance of "Ether Day" was established. The old amphitheatre was used as an operating room until the early part of 1868, when a surgical building was opened, and named the Bigelow Amphitheatre in honor of Dr. Henry J. Bigelow a noted surgeon of the staff.

"Outdoor patients" were probably received at the hospital early in its existence, though no definite reference to them is found in the annals of the institution until 1844. Two years later it was voted that books be "ordered to be kept as a record of all outdoor patients." In 1883 a building was erected exclusively for this class of patients. This served until 1903 when it was replaced by a very large and splendidly equipped building. With continued growth, however, and the establishment of many special clinics, this, too, has been outgrown, and the addition of an extra story is now contemplated.

During the '70s and '80s a group of "pavilion" wards sprang up. The first were built in 1873 and were the only ones of that type in this part of the world. In 1882 a Convalescent Home was opened for patients discharged from the hospital who had no suitable place in which to recover their complete strength. The funds for this building were raised largely at the suggestion, and through the efforts, of one woman, Miss Mary A. P. Russell. This "home" is in Waverley, Mass., on a part of the land to which the McLean Hospital was transferred in 1895.

In 1873 the Boston Training School for Nurses was established, and was allowed to practice nursing in this institution, but under very exacting rules and regulations. In spite of ample proof of its value within within the hospital walls, it was twenty-three years later that the school was formally taken over by the trustees, and became the Massachusetts General Hospital Training School for Nurses.

The Warren Library, for the use of patients, was established in 1841, when Dr. John C. Warren, already mentioned, made a gift of $1,000 as a fund "for the purchase of religious and moral books to be given to patients on leaving the hospital." Gradually the type of books has broadened, and their use has

extended to all persons connected with the hospital. It is no longer a *giving,* but a *lending* library, and is presided over by a trained librarian whose work bears a very vital relation to the treatment of patients. This was the first library of its kind in the country, if not in the world.

The Treadwell Library—the medical library—has been in existence for nearly eighty years, and stands today among the foremost of hospital medical libraries. It numbers some 12,000 volumes, and serves the needs of the scientific personnel of the institution. It is now housed in handsome quarters on the second floor of the Moseley Memorial Building erected in 1916. This building is the entrance to the hospital, and in it are located all the offices connected with administration. Rooms for the accommodation of house officers occupy the upper floors above the Treadwell Library. The Record Room is on the second floor, closely connected with the library, and here may be found clinical records dating from the day the hospital opened. Good records began with the first patient. Both Dr. Jackson and Dr. Warren set a high standard for this work, and it has been followed throughout. Such records offer much to medical history, and provide an unfailing source of information in the investigation of disease. Careful cataloguing has made them available, and no record has ever been destroyed.

Since 1900 a new Surgical Building has taken the place of the Bigelow Amphitheatre (although the name is still preserved); a Domestic Building, for kitchens, dining rooms and maids' quarters has been added; special wards for the care of dermatological and orthopedic patients have been erected; a second "Home" for nurses has appeared; and the Phillips House, an exclusive private ward, has been opened. The Pathological Laboratory has occupied a building by itself since 1896, and during this period has been under the able management of Dr. J. Homer Wright.

During the last two years the Bulfinch Building has been entirely fireproofed, the ells have been added at each end, largely for the accommodation of medical and surgical laboratories, and for the offices of certain staff members. There is now in contemplation a hospital for people of moderate means. This will be an eleven story building, and will be modern in every respect. It will fill a long felt need in the community. Other improvements are presenting, and are lacking only funds to be put into execution.

The disease now known as appendicitis was first correctly diagnosed by the late Dr. Reginald Heber Fitz, then microscopist to the hospital. The original manuscript of his famous paper on the Vermiform Appendix is preserved in the Treadwell Library. It was published in 1886 in the *American Journal of the Medical Sciences.*

The discovery of x rays was announced in December, 1895, and before the end of that year their use in the diagnosis of disease was undertaken at the Massachusetts General Hospital. Dr. Walter J. Dodd was then head pharmacist and photographer, and it was through his efforts that the first investigations were begun. He became a pioneer in this work, and finally died, in 1916, from the effect of burns received long before their danger was realized. His name is written in letters of gold in the hearts of his many friends. His last work was done overseas, with the first Harvard Medical Unit during the World War, and for this he received citation from the British Government.

In 1905 came the organization of Social Service. Dr. Richard C. Cabot was its founder and has been its inspiration during the twenty-one years of its existence. In the clinics of this Out-Patient Department he early recognized that the personal element enters largely into the treatment of disease; that it was futile, for instance, to recommend a long vacation to a patient for whom it was an absolute impossibility; or a surgical operation with its attendant difficulties to a woman—the mother of five or six little children, and with no one to care for them during the period of her incapacity—and he undertook the solution of the problem. The results of his work are too well known to need remark here, for Social Service has spread far beyond the confines of this country.

It was this same physician who began, in 1915, the circulation of the *Cabot Case Records,* in which clinical studies with discussion by groups of consultants are supplemented by postmortem findings. This publication, garnered from the clinical records of the hospital, goes far abroad and is of value not only to physicians and students singly, but it provides exercises in diagnosis for many groups of physicians in other cities, and in the rural districts of this and other countries. Three cases are published each week in the *Boston Medical and Surgical Journal.*

In 1911 the visiting staff of physicians and surgeons was entirely reorganized, and the first paid nearly full time member appointed, Dr. D. L. Edsall, now dean of the Harvard Medical School. The beginning of a new organization of research was encouraged by Dr. Edsall. Since then several men have received similar appointment, and the teaching element in the hospital has greatly increased.

A Consultation Clinic was opened in January, 1916, at which persons, recommended by their own physicians, and upon the payment of a nominal fee, may obtain the combined advice of different medical specialists now necessary for a thorough diagnosis and rational treatment of disease. This was an innovation in medical service, and has proved of value.

In the three wars which have occurred during the period of its existence, the Massachusetts General Hospital has been found ready and willing to contribute to the relief of suffering and wounded soldiers. In 1861 the secretary of the trustees was directed to communicate to His Excellency, Governor Andrews, the following vote, "That the Trustees of the Massachusetts General Hospital assure the Executive of the Commonwealth that, in the event of any diseased or wounded soldiers being returned to this city, they shall consider it their duty and privilege to extend to them all the succor and relief that may be within their power." Governor Andrews later expressed his high appreciation of the attentions rendered by the hospital to returned soldiers.

During the brief period of the Spanish War in 1898, tents filled with cots were put up on the lawns about the hospital, and every spare bed in the wards was utilized, for the care of men brought to this port in hospital ships. Typhoid fever and malaria were the prevailing disease. The surgical cases received were very few.

When the United States entered the World War, the Massachusetts General Hospital was one of the few large American hospitals ready to take the field with a fully equipped base hospital. The order to move came on July 9, 1917, and the unit started across seas under the command of Major Frederic A. Washburn, resident physician and administrator of this hospital. The unit was located in France, not far from Bordeaux, and here, under the direction of its commander, a military hospital of nearly one hundred wards, and approximately five thousand beds, grew up.

The splendid work accomplished by the entire personnel would fill an article by itself. On the day of the signing of the armistice there were 4,319 patients under care. The last members of the unit did not reach home until March 2, 1919. Graduates of this hospital served also with the British Army, and on the staffs of four other base hospitals besides its own. Of commissioned officers, the Massachusetts General Hospital supplied 275, and 290 nurses. The successor of United States Army Base Hospital No. 6 is General Hospital No. 6, now organized as a part of the Army Reserve for Medical Service in a future military emergency.

This article would not be complete without a mention of famous men who have served during their best years as physicians and surgeons. The name of Warren has always been found on the list—father, son and grandson—the last now retired from active service, but still on the Board of Consultation. Dr. James Jackson, contemporary of the first Dr. Warren, had no son upon whom his mantle might fall, but it has been honorably worn by Putnams and Minots —direct descendants of Dr. Jackson. In the far past appear the names of John Jeffries, Oliver Wendell Holmes, Jacob Bigelow, Henry I. Bowditch, Samuel Cabot, and many others who have made large contributions to the science of medicine. The late Dr. Herbert B. Howard, the predecessor of Dr. Washburn, present director of the institution, was one of the speakers at the opening of the Moseley Memorial Building, already mentioned. The following is quoted from his remarks: "About the time I came here as resident physician (1897), while on a visit to New York City, I met the senior surgeon to the Presbyterian Hospital. He asked me to name the surgeons at the Massachusetts General Hospital. I said: 'Dr. Porter, Dr. Warren, Dr. Beach, Dr. Homans, Dr. Cabot (Arthur T.), Dr. Richardson, Dr. Eliot, Dr. Harrington, Dr. Mixter.' He then said: 'Young man, there are many hospitals that have one or two such men, but there is no other hospital that has nine.' He might have added: 'Or that has six such physicians.'" The latter were then Dr. W. L. Richardson, Dr. F. C. Shattuck, Dr. Fitz, Dr. Cutler, Dr. Gannett, Dr. Vickery. In many instances, a father has been followed by his son, until the personnel of the hospital today, both medical and administrative, is like that of one great family.

Such men contribute the best that is in them, and pass on leaving the institution so much the richer. Tradition grows out of their lives and their deeds. As they go in and out of a great hospital, day after day and year after year, something of their personality passes into the institution itself, and out of it grows a splendid composite life.

News Items.

Plans for Accident Conference.—Plans for an accident prevention conference, to meet during the summer in Washington, D. C., are under consideration by Secretary Davis of the U. S. Department of Labor. All industrial and commercial enterprises of the country will be invited to send their representatives.

Institute of Euthenics at Vassar.—An institute of euthenics "for the study of certain phases of human relationship and environmental influences" will be held at Vassar College, Poughkeepsie, New York, July 8th to August 8th. The lecturers will include authorities of international reputation.

Visiting Psychiatrist in Boston.—The Boston Federation for Placement Work and the Massachusetts Society for Mental Hygiene have organized a cooperative plan, according to the *Mental Hygiene Bulletin*, whereby the services of a visiting psychiatrist will be made available to certain social service agencies in Boston. Dr. Elizabeth A. Sullivan has been engaged as visiting psychiatrist.

Wiesbaden Research Institute.—Wiesbaden, Germany, has perfected plans for a research institution for balneology and metabolism, to operate in close cooperation with the various scientific institutions of the health resort. The establishment of such an institution has long been advocated, not only by physicians, but also by administrative and industrial concerns as of importance from an economical as well as from a medical point of view.

Promotions at College of Physicians and Surgeons.—Dr. Louis Bauman, Dr. Henry T. Chickering, Dr. Robert L. Levy, Dr. I. Ogden Woodruff, associates in medicine, have been appointed assistant professors of clinical medicine; Dr. George C. Andrews, Dr. A. Benson Cannon, instructors in dermatology, to be assistant professors of dermatology; Dr. Hugh Auchincloss, associate professor of surgery, to be professor of clinical surgery; Dr. William C. Clark, associate professor of surgery, to be professor of experimental surgery; Dr. Fordyce B. St. John, associate professor of surgery, to be professor of surgery; Dr. George M. Mackenzie, assistant professor of medicine, to be associate professor of medicine.

Fiftieth Anniversary of Johns Hopkins.—The celebration of the fiftieth anniversary of the founding of Johns Hopkins University will take place on October 23rd. The chief events of the occasion will be the dedication of the new million dollar building of the School of Hygiene and Public Health; a series of conferences to be addressed by leaders in the social and natural sciences; commemorative exercises, and an alumni banquet. Among the speakers will be: Dr. Andrew Balfour, director of the London School of Hygiene and Tropical Medicine; Professor Neufeld, director of the Institute of Infectious Diseases, Berlin, who will deliver the De Lamar Memorial Lecture; Prof. Levy-Bruhl of the department of modern philosophy at the Sorbonne; Albert C. Ritchie, Governor of Maryland, a Johns Hopkins alumnus; Mayor Howard W. Jackson of Baltimore; Newton D. Baker, former Secretary of War; Prof. Edwin G. Conklin of Princeton University; Dean Gordon J. Laing of the Graduate School of Arts and Literature at the University of Chicago, and others. Dr. Ira Remsen, the only surviving member of the original faculty of the university, will attend the celebration.

Personal.—Dr. L. R. Thompson, of the U. S. Public Health Service, has been placed in charge of the study of effects of cotton dust upon the respiratory organs of workers now being conducted in Greenville, S. C.

Dr. Charles Bernstein, superintendent of the Rome State School, New York, will give a lecture course at the twelfth annual summer school to be held during July and August at the Rome State School.

Dr. Paul J. Ewerhardt has accepted the position of director of the extramural clinics of the Rhode Island Society for Mental Hygiene.

Jane M. Hoey, assistant director of the Welfare Council of New York City, is the only woman appointed by Governor Smith to serve on the recently named commission of eleven to examine the crime situation in New York State.

Dr. Shirley Wynn addressed the joint meeting of the New York Committee on Baby Health Stations and the New York Committee on Pre-school Clinics and Nutritional Classes of the Children's Welfare Federation at its June meeting.

Society News and Notes.

Meetings of the New York Academy of Sciences were discontinued at the end of May; they will be resumed in October.

At the last annual stomatological convention held in New York City at the Academy of Medicine, the following were elected to honorary membership in the American Stomatological Association: Sir William Arbuthnot Lane of London, England; Prof. A. Cieczynski of Lwow, Poland; Prof. Coen Cagli of Rome, Italy; Prof. A. Herpin of Paris, and Prof. Joseph Szabo of Budapest.

* * *

The National Association for the Study of Epilepsy held its twenty-fifth annual meeting at the Waldorf Astoria, New York, June 7th-8th. Among those who presented papers were Dr. Wuth, Dr. Clark, Dr. Patterson, Dr. Jelliffe, Dr. Clausen, Dr. Alford, Dr. Brill, Dr. Elsberg, Dr. Gordon, Dr. Sullivan, Dr. Peckham, and Dr. Hodgkins. The meeting immediately precedes that of the American Psychiatric Association, and American Psychopathological Association.

* * *

Physical education societies in Czechoslovakia have received from the ministry of public health of that country subsidies representing a total of 4,450,000 crowns to be devoted to furthering their work. In addition a sum of 1,800,000 crowns has been granted to assist in building gymnasiums, playing fields, and training grounds of various kinds. The Czechoslovakian people are greatly interested in the physical culture movement, as is evidenced by the membership of the Association of Workmen's Gymnastic Societies which number 96,606 persons, and that of the Federation of Workmen's Gymnastic Societies, with 94,981 members.

Book Reviews

THE RESPIRATORY FUNCTION OF THE BLOOD

The Respiratory Function of the Blood. Part I: Lessons from High Altitudes. By Joseph Barcroft. Cambridge: The University Press, 1925. Pp. 207.

This book is not only an authoritative monograph on the physiological reaction and adaptation of the human body to high altitudes, but a fascinating narrative as well. It is based largely on the 1921 expedition to the Andes in central Peru, led by the author. Owing to the rapid advance of knowledge, Mr. Barcroft found it impossible to revise his original volume on *The Respiratory Function of the Blood* for a second edition. He therefore decided to break up the work into a series of manageable units, of which this is the first volume. Following a clinical description of mountain sickness and of the native dwellers at high altitudes, there are chapters on the color of the face and its significance, muscular exercise, the hydrogen ion concentration of the blood, the pulse, the circulation rate, the heart, the red corpuscles, and the mind. The final chapter discusses all the facts on acclimatization. The oxygen deficiency of the atmosphere results in an increased total ventilation of the lungs with a resultant drop in the carbon dioxide content of the blood. There is an increase in hemoglobin and in the number of red blood cells, as well as a shift in the dissociation curve. The actual symptoms of mountain sickness are due to oxygen want in the medulla. In the appendix are found notes on the physiological difficulties in ascending Mount Everest.

This book is to be recommended to the general medical public, as well as to the specialist, as a very readable and thorough summary of certain aspects of the respiratory function of the blood, as illustrated by experiments and observations at high altitudes.

TREATMENT OF GONORRHEA IN THE MALE

Die medikamentöse Behandlung der Harnröhrengonorrheoe des Mannes und deren pharmakologische Gründlagen. By Dr. Alfred Perutz. With 13 Illustrations. Berlin and Vienna: Urban & Schwarzenberg, 1925. Pp. 266.

The author stresses the importance of a knowledge of the nerve supply of the genitourinary apparatus in the male, with special reference to its particular reaction towards the drugs and chemicals employed in the treatment of gonorrhea. This is in keeping with the main purpose of the book, namely to consider the therapy of gonorrhea in the male from the viewpoint of medicopharmacology. The specific action of well known and some obscure drugs is considered at length, the author emphasizing the consequences of producing antagonistic effects by the careless employment of chemical bodies which may be incompatible or antagonistic in therapeutic effect.

Active and passive immunization and the serodiagnosis of gonorrhea are discussed at length. Parenteral protein therapy, widely employed in Germany, constitutes a most valuable chapter. Abortive methods are thoroughly considered, though we fail to find any mention of the "sealing in" method favored in this country.

A bibliography with approximately a thousand names adds value to the work. It is gratifying to find a few American names in the list; this is somewhat unusual in foreign medical works of this kind.

The work possesses considerable value to the venereologist. It is fully up to date and international in scope. American chemicals are intelligently and fairly considered. The German reading urologist will find the work most useful.

PULMONARY ARTERITIS

La Arteritis Pulmonar y su Cuadro Clinico. By F. C. Arrillaga. Buenos Aires: Pedro Garcia, 1925. Pp. 274.

This monograph represents a comprehensive study of the syndrome due to sclerosis of the pulmonary arteries, often called Ayerza's Disease. This illness is characterized by intense cyanosis, enlargement and failure of the right ventricle and a characteristic bulging of the enlarged pulmonary artery on the röntgen plate, in the absence of signs of mitral stenosis or pulmonary emphysema, which might produce a similar picture. It is usually syphilitic in origin and Arrillaga conceives of the process as a luetic bronchopneumonia which secondarily involves the smaller pulmonary arteries. He presents an excellent historical résumé with references to all of the important literature. The pathological anatomy is discussed in the light of many autopsies and is well illustrated. Many case reports are included to elucidate the symptomatology. The reproductions of characteristic x rays are particularly valuable. The striking appearance of the patients, which has given them the picturesque name of *cardiacos negros,* is well shown in colored photographs. Dr. Arrillaga is to be congratulated on the production of an excellent monograph, and the publisher on the general makeup of the book. It is to be hoped that it will be translated into a language more widely read than Spanish.

FACTS ON THE HEART

Facts on the Heart. By Richard C. Cabot, M. D., Professor of Medicine and Social Ethics, Harvard University. With 163 Illustrations. Philadelphia and London: W. B. Saunders Company, 1926. Pp. 781.

This book resembles in many respects Dr. Cabot's well known volumes on differential diagnosis. It is based on a review of 4,143 lesions in 1,906 necropsied cases of heart disease done at the Massachusetts General Hospital between 1896 and 1919. In the initial chapter there is a brief review of the material studied. It is remarkable that in Table I, in which the whole material is summarized, not a single case of socalled emphysema heart, that is, hypertrophy, dilatation and failure of the right ventricle secondary to pulmonary emphysema, is recorded, while there are 156 cases of hypertrophy and dilatation of the heart unaccompanied by other lesions, and 668 cases of hypertrophy and dilatation associated only with arteriosclerosis. Now it is common knowledge that right ventricular hypertrophy and dilatation secondary to pulmonary

emphysema is very common, and that socalled idiopathic hypertrophy is very rare, and that arteriosclerosis alone rarely causes cardiac hypertrophy. This table thus illustrates the inevitable and almost insuperable difficulties involved in any such study in which material studied and gathered by many men, with varying standards and varying nomenclature, is integrated into a comprehensive study by one man. From a statistical point of view there are bound to be many inaccuracies. Another illustration of this difficulty is the group of cases classed as nephritis and arteriosclerotic degenerated kidney. There is no clear distinction made between glomerulonephritis, arteriosclerosis with hypertension, and the gross scars following sclerosis of the larger renal arteries.

Subsequent chapters are devoted to a more detailed study of rheumatic, syphilitic, and hypertensive heart disease, myocarditis, angina pectoris, endocarditis, pericarditis, and thyrocardiac disease. Many interesting case reports with necropsy findings are included in each chapter. The final chapter is a summary of the book. Some of the conclusions are not quite convincing. From an extensive necropsy experience in a large hospital with a rich cardiac material the reviewer cannot agree that over one half of cases of mitral disease are not recognized during life. It is certain that Dr. Cabot's personal percentage of correct diagnoses of this condition is much higher, and so is that of many competent careful physicians. With most of the other conclusions the reviewer is in accord. Dr. Cabot found hypertensive heart disease twice as common in men as in women, whereas, in the experience of the reviewer and of others, about two thirds of the cases of hypertension occur in women. There is much that is of value in the book, a vast amount of material sifted and classified and illuminated by critical comments of an experienced clinician. It suffers from the inevitable defects and inaccuracies of a work that is a compilation of the observations of many men, extended over a period of twenty-five years, during which time the concepts of heart disease and the terminology applied to it have undergone such fundamental changes.

REJUVENATION

Scientific Rejuvenation Without Operation. The New Science of Radiendocrinology in Its Relation to Rejuvenation and the Relief of Common Ailments Based on the Radiation Technic of Dr. Eugen Steinach. New York: Medical Science Publishing Company, 1923. Pp. 64.

The author of this little book is not named—except that he is termed "one of America's foremost radiendocrinologists," who wrote the book "in collaboration with associated physiologists, endocrinologists and physicists."

However, this book is only the "popular edition" of one that was published in 1923 by the "Medical Science Publishing Company," and its author was named there as Dr. Herman H. Rubin.

There may be two reasons for omitting the author's name in the new edition: he may feel ashamed to admit authorship of the book—if this is so, he is right; or it may be that he did not want any other name to appear on the title page than the name of Dr. Eugen Steinach of Vienna. Perhaps to make it appear to a careless reader that Steinach himself wrote the book? If the latter, however, is true, its criticism would belong in a law court and not in a medical review.

The little book itself seems to have only one purpose: to emphasize the alleged fact that radiation of the endocrine glands, with an apparatus called radiendocrinator, is superior to all other methods of "rejuvenation," which by operation or by x ray, and that practically all ailments of the human body can be cured with this apparatus, which "for the ionization of the ductless glands by gamma rays" is said to contain radioactive elements "one hundred times more active and one hundred times more expensive than radium."

After explaining some fundamental facts of the endocrine glands and their functions in a language more than popular, the author discusses "rejuvenation" treatments, especially the Steinach operation (vasoligation). He further attempts to explain "ionization of body tissues," ascribing to Steinach the discovery of "radiation rejuvenation" and finally comes to the description of the aforementioned radiendocrinator, which he calls "the most efficient device yet produced for the Steinach treatment of rejuvenation by radiation." He further describes it as an "extremely complex apparatus," "a silent generator of stupendous electronic energy, having several times the voltage of the most powerful x rays ever produced." In spite of this alleged power of the apparatus, the book goes on to explain that the devices are "primarily worn at night while asleep" and that they furnish a "home rejuvenation treatment."

It must be left to the reader to form an opinion as to the real physical properties of the radiendocrinator and its scientific justification.

In the opinion of radium experts, a tremendous amount of radium would be necessary to produce sufficient gamma rays to—for instance—reach a woman's ovaries at a depth of from seven to ten centimetres underneath the skin. It is utterly inconceivable that any apparatus could contain any such amount of radium, but still the treatment of the ovaries is one of the chief tasks of the radiendocrinator.

In the last chapters claims are made of alleged cures of various ailments, however too unfounded to justify a more detailed review.

After reading of about sixty diseases and symptoms as successfully treated by radiendocrination, a paragraph at the beginning of the book takes on special significance. It reads: "The publishers of this book have received so much correspondence from readers concerning the subjects contained herein that they take this opportunity in this issue of explaining that the special means for utilizing the Steinach technic can be obtained only from those holding rights in this country, the American Endocrine Laboratories. *Sapienti sat.*

No laboratory tests, no animal experiments, no carefully written up case histories, no control photos and no regular scientific publications exist—as, for instance, for the Steinach operation and for the x ray treatments of endocrine disorders, to support the claims for the "radiendocrinator." Only Steinach's good scientific name is used to lend weight to utterly unsupported statements. Again and again the reader is made to believe that Professor Steinach himself is

using "the radiation technic" that is expounded in this publication. But this is utterly untrue.

"The Steinach method of rejuvenation" consists of vasoligation in men and chiefly of diathermy treatments in women. Steinach's alleged experiments and treatments with "endocrine ionization" is a pure fabrication. A publication like this little book is a great misfortune and does tremendous harm. It is this kind of a publication that is responsible for the antagonism of the medical profession towards certain phases of endocrinology and especially towards "rejuvenation" and the Steinach methods, and for its misconceptions and distrust prevailing among the intelligent laity.

On the whole, the little book can only be called a most astonishing product of charlatanism, speculating on the power of advertising methods and on the credulity of an uneducated public.

ACTIVITIES OF THE ROCKEFELLER FOUNDATION

Annual Report of the Rockefeller Foundation for 1924. Illustrated. New York: Rockefeller Foundation, 1926. Pp. 447.

During the year 1924 the International Health Board of the Rockefeller Foundation, the China Medical Board, the Division of Medical Education, and the Division of Studies took part in the inauguration or development of nineteen different lines of activities along medical lines, which may be briefly summarized as follows:

1, Helped finance a plan for establishing an international abstract journal of the biological sciences; 2, began to issue bulletins reporting progress of medical education in many countries; 3, helped to spread internationally knowledge about medical equipment and teaching methods through surveys by staff members, commissions of scientists, visiting professors, and traveling fellows; 4, hastened developments in the medical schools of the Universities of Oxford, Cambridge, Edinburgh, Wales, Montreal, McGill, Sao Paulo, Hongkong, and Siam, and of the American University of Beirut; 5, maintained a modern medical school and teaching hospital in Peking; 6, aided three other medical schools and seventeen hospitals in China; 7, helped to improve the teaching of physics, chemistry, and biology in two Chinese and nine foreign institutions in China and in the Government University in Siam; 8, had a part in the development of professional training for sanitarians and hygienists at Harvard and in schools and institutes in London, Prague, Warsaw, and Sao Paulo; 9, gave funds for nursing education at Yale and in schools and hospitals in Brazil, France, Yugoslavia, Poland, and the Philippines; 10, kept a mobile staff on guard against yellow fever in Mexico and Central America; 11, at the request of Brazil, joined in an attack upon this disease from eleven centres along the coast; 12, helped to show the possibilities of malaria control in thirteen American states and made malaria surveys or studies in Haiti, Porto Rico, Nicaragua, Brazil, Italy, Palestine, Queensland, and the Philippines; 13, either continued or began antihookworm work in conjunction with thirty-two states and countries in the West Indies, Central America and Mexico, South America, Europe and the Far East; 14, contributed to the budgets of rural health services in 207 counties in twenty-four American states and in New Brunswick, Brazil, France and Czechoslovakia; 15, continued to aid the epidemiological intelligence service of the Health Section of the League of Nations; 16, contributed to the League of Nations' international study tours or interchanges for ninety-nine health officers from twenty countries; 17, provided directly or indirectly fellowships for 864 individuals of thirty-three different nations; 18, lent staff members and made minor gifts to many governments and institutions for various kinds of counsel and aid; 19, assisted mental hygiene projects both in the United States and in Canada, demonstrations in dispensary development in New York City, the growth of antituberculosis work in France, and other undertakings in public health, medical education and allied fields.

The report of the foundation describes and discusses in some detail each one of these various activities, with excellent illustrations which add interest to the text, and a large number of charts and statistical tables, maps and plans. The president, Mr. George E. Vincent, in closing his review of the work for 1924, writes: "This summary story of a year's activity records cooperation with thirty-two commonwealths of the United States of America and with seventy-seven other states and countries. . . . The Rockefeller Foundation within its chosen field seeks to share in the common task as a means of realizing the purpose of its charter, the wellbeing of mankind throughout the world."

INTESTINAL TUBERCULOSIS

Intestinal Tuberculosis. Its Importance, Diagnosis, and Treatment. A Study of the Secondary Ulcerative Type. By Lawrason Brown, M.D., and Homer L. Sampson. Philadelphia and New York: Lea & Febiger, 1926. Pp. 304.

This is another of the monographs that fills a unique niche in medicine. The nearest approach to covering the same subject is Fenwick's *Dyspepsia of Phthisis,* now over thirty years old. A comparison of the two works offers a striking lesson in the growth of our knowledge—a growth due primarily, of course, to the introduction of the x rays.

The röntgen studies appear, on the whole, unusually sound. It might be desirable to devote more space to the differential diagnosis between tuberculous and nontuberculous (simple) colitis, the latter being a far more common condition than is generally realized. It must be granted, however, that the checks on the work, as far as the authors' material permits, seem carefully planned and well executed.

LEAD POISONING

Lead Poisoning. Medical Monographs. Vol. VII. By Joseph C. Aub, Lawrence T. Fairhall, A. S. Minot and Paul Reznikoff. With a Chapter on the Prevalence of Industrial Lead Poisoning in the United States by Alice Hamilton. Baltimore: The Williams and Wilkins Company, 1926. Pp. 265.

In this useful book are treated the chemistry, pathology, and physiology, as well as the clinical aspects of lead intoxication. The chapter on history is exceedingly interesting. The work appeals to many interests—the clinician, the biochemist, the physiologist, the industrial chemist, the sanitarian.

The style is exceedingly clear and easy to follow. The absence of an index is an obvious disadvantage. It would be, to our mind, at least as useful as the excellent bibliography which accompanies the volume.

Medicoliterary Notes.

The publishing firm of Paul B. Hoeber, Inc., New York City, has purchased the *American Journal of Surgery,* a medical magazine that has existed for more than twenty years. Dr. Walter M. Brickner, editor in chief of the journal since its establishment, will continue to hold the position, assisted by a staff of distinguished physicians and surgeons.

* * *

Insanity is increasing in Vienna. Statistics just issued show a rise of fifteen per cent. over last year. A large percentage of the new cases are women. Doctors ascribe the phenomenon to nerves weakened by the strain of postwar worries now breaking down as people of mature age continue to brood over their past troubles.—*N. Y. Times.*

* * *

Two important articles in *Mental Hygiene* for April are the Significance of Psychoanalysis in Social Life, by Otto Rank of Vienna, and Insanity and Crime, by Dr. William A. White of St. Elizabeth's Hospital, Washington, D. C.

* * *

A decree recently issued by the government of Bolivia requires that children of twelve and under can attend moving pictures only on holidays, and then are limited to seeing the pictures authorized by the police. It is believed that this move will safeguard in some degree the morals and welfare of the younger children.

* * *

Sylvia Townsend Warner, author of *Lolly Willowes,* the story of a selfeffacing spinster who sought escape from her life of English propriety by becoming a very respectable and proper witch, is a niece of Arthur Machen, a fact which could escape no reader of her book who is acquainted with the work and philosophy of her uncle.

* * *

According to a recent announcement by Dr. Ko-Kuel Chen, pharmacologist of the University of Wisconsin, new uses have been discovered for an ancient Chinese drug called ephedrine, indicating that it is a powerful aid in raising blood pressure, in the treatment of asthma and colds, and as an anesthetic. Ephedrine has been in use in China for more than five thousand years, according to Dr. Chen, who asserts that he has found a new method for isolating the drug, which has been submitted to tests at the Mayo Clinic and at the University of Pennsylvania.

* * *

The *Long Island Medical Journal* for February contains an interesting article by Charles Frankenberger, Librarian of the Medical Society of the County of Kings, Brooklyn, entitled How to Consult the Medical Library and Medical Literature. It is a practical paper containing many helpful suggestions for those who have occasion to use or to consult medical material.

* * *

In times of peace soldiers have the lowest mortality rate of any class of men, the death rate being only five in every thousand. Probably clergymen are popularly considered as leading the most placid lives in modern life; yet a comparison of rates shows that the annual death rate among the ministry is more than twice that among soldiers, being eleven in every thousand.

* * *

Psychoanalysis has finally appeared on the movie screen. In Berlin a film was recently shown called the *Secret of the Soul,* which is reported to illustrate Freud's method and technique in psychological analysis. Freud himself was present to describe the case. Work on the film was begun by the late Dr. Carl Abraham, and completed by Dr. Hans Sachs.

* * *

In the new medical school and hospital of the University of Colorado at Denver, the color problem for walls and furnishings has been worked out in detail. The x ray room has walls of a violet red, which has great light absorption power, yet exerts a quieting influence on the patient, and is slightly stimulating to the operator. In the operating theatre a soft gray is used. The wards for disturbed patients have yellowish green walls because this color has been found to have a tranquilizing and cheerful influence. Rooms with a northern exposure have yellow walls, and those with a southern outlook with sunshine gray walls and furnishing.

* * *

Two old sun dials recently discovered in Ireland are reported to prove that daylight saving time is no new practice, but existed for many hundreds of years before the twelfth century A. D. The ancient Irish hour varied in length, according to those who have studied the dials, with the season of the year and the latitude. In Ireland the daylight hour in midsummer was eighty minutes, and in winter only forty.

* * *

The Renaissance Theatre of London has revived the play entitled, the *White Devil,* by John Webster, who was the father of John Webster, fifth colonial governor of Connecticut, and founder of the Webster family in America. The late Dr. David Webster, for many years head of the Eye and Ear Hospital, New York, was of the Tory Canadian branch of this family. Dr. John Stuart Thomson, literary executor of the Webster Thomson family, is the author of a number of books and articles on the opium evil, with which he had extensive contact in its native lair as manager of the Pacific Mail and other steamship companies at Hong Kong. Dr. Thomson will be one of the chief speakers at the world conference on opium which has been called by Congress to be held in July in Philadelphia.

* * *

At a recent theatrical performance in Leningrad, which included a William Tell act in which a performer shot an an apple from his brother's head, a bullet went wild and struck the orchestra leader, Sergius Novitsky, in the mouth, shattering some of his teeth and tearing away part of his nose. Novitsky retained his selfpossession to such an extent that no one in the audience was aware of the accident, and he continued to conduct his orchestra until loss of blood caused him to collapse.

* * *

Evidence that the bodies of men and animals are not quite so exacting in their protein food demands as biochemists had supposed has been obtained from experiments in nutrition recently performed at the University of Illinois by Dr. William C. Rose and Dr. Gerald J. Cox. These experiments resulted in the successful use of an artificial product to replace histidine, which was previously thought to be one of the twenty building stones of protein essential to the growth and development of men and animals. The successful substitute is imidazole lactic acid.

* * *

A Dutch scientist, assuming that talking fatigues women less than it does men, explains this by the statement of two facts: first, that the greater the length of the vocal cords, the more energy is required to produce a sound; second, that the vocal cords of women are shorter than those of men.

* * *

Diseases of bees, silkworms, fishes and even plants, caused by protozoa, may be banished by means of oxygen applied under pressure, according to Dr. L. R. Cleveland, of the Harvard University Medical School. Dr. Cleveland's earlier work on the effects of oxygen on protozoa and their insect hosts won for him half of the annual prize of the American Association for the Advancement of Science at its Washington meeting in 1924.

* * *

Recent publications of interest to the medical profession are: *Strength of Religion as Shown by Science,* by Dr. Charles E. de M. Sajous (F. A. Davis Company); *Light and Heat,* by M. Luckiesh and A. J. Pacini (Williams & Wilkins, Baltimore); *The Adventures of Old Age,* by Francis Bardwell, with an introduction by Dr. Richard C. Cabot (Houghton Mifflin); *Your Food and You,* by Ida C. Bailey Allen (Doubleday, Page); *Reluctantly Told,* by Jane Hillyer, with an introduction by Dr. Joseph Collins; *Our Minds and Their Bodies,* by John Laird (Oxford University Press); *Betterman II on the Business of Medicine,* by Dr. Charles E. Blanchard (Medical Success Press, Youngstown, O.); *Through a Consulting Room Window,* by Dr. W. C. Rivers of London; *The Theory of the Gene,* by Thomas Hunt Morgan (Yale University Press); *Healthful Control in Mercantile Life,* by Arthur Brewster (Harper); *Havelock Ellis,* by Isaac Goldberg (Simon & Schuster); *Outline of Abnormal Psychology,* by William McDougall (Scribner).

Seventy-seventh Annual Meeting, Dallas, Texas, April 19-23, 1926

(*Concluded from page 777*)

The Scientific Proceedings

SECTION ON RADIOLOGY

CHAIRMAN, DR. A. C. CHRISTIE, OF WASHINGTON.
SECRETARY, DR. W. J. HUBENY, OF CHICAGO.

Radon as a Palliative Agent in the Treatment of Intraoral Cancer.—Dr. Frank E. Simpson, of Chicago, said that there were two phases to intraoral cancer—the intraoral lesion and the adjacent lymph nodes in the neck. In the treatment of intraoral cancer, the distinctly operable case might receive the benefits of surgery, all other cases might be treated with radium. Operable lesions were small, well localized and easily accessible. Inoperable lesions were larger, ill defined and inaccessible. The use of not less than one thousand mc. of radon was necessary for surface applications to the intraoral lesion. In certain cases and always in tongue cancer he advised, in addition, the insertion of bare glass tubes containing from 0.5 to 1 mc. of radon. Nurses and others who handled large quantities of radium must protect themselves against its local and constitutional effects. The adjacent lymph nodes might be treated by the surface application of not less than one thousand mc. of radon. The general results in fifty-six cases showed twenty patients (35.7 per cent.) had been living and well for a period of from three to five years.

Hodgkin's Disease and Lymphosarcoma, With Especial Reference to Their Treatment by Radiation.—Dr. Curtis F. Burnam, of Baltimore, Md., said that his paper dealt for the most part with the treatment of Hodgkin's disease, lymphogranulomatosis. In reviewing the history, symptomatology, gross and microscopical anatomy, he pointed out that certain glandular forms of tuberculosis and syphilis, true leucemia, and pseudoleucemia, as well as endothelioma, can only be definitely excluded by a biopsy and microscopical study of the tissue. Blood examinations are essential in differentiating the leucemia, and, while not characteristic for Hodgkin's disease, are helpful. The etiology is still in the dark. The disease bears the earmarks of a chronic infection. In spite of the negative inoculation results, he said that a considerable number of authorities still hold to a tuberculous association of some sort. The pleomorphic diphtheroid organism, described by Bunting and Yates, does not seem to have a definite causative relationship. The cardinal symptoms are gland and splenic hypertrophies, fever, pruritus, and weakness. To these are superadded the pressure phenomena and physiological disturbances, varying greatly with the part of the body involved. The pathology fixed by Sternberg and Dorothy Reed is established.

No specific drug or serum has been discovered. Arsenic in many forms has been used and often helps. Among general measures, removal of focal infection, rest and nutritional care, are of distinct value. Operative surgical removal should be limited to cases where only a single, easily removable group of glands is involved. X radiation, first employed by Pusey, in 1902, is the most generally used method of treatment. With the exception of the acute fulminant cases, it nearly always improves conditions. In many cases it leads to temporary, clinical cures, and in a few cases to freedom from all symptoms for a time long enough to be regarded as permanent. The author stated that he had treated his own cases almost entirely by the radium pack method, which he described in detail as well as x ray methods. He was inclined to believe that radium was somewhat more effectual and less likely to do injury than x ray.

Of 149 patients treated and observed for over one year, 112, after periods varying from one to nine years, have died of the disease; nine of the remaining patients are living in periods varying from two to six years, with evidence of the disease; two patients died in the ninth and tenth years without evidence of the disease, and apparently from other causes; twenty-six patients are living and clinically well; eleven of these twenty-six patients for periods ranging from five to ten years, and five of the eleven cases, for periods of more than nine years.

SECTION ON PATHOLOGY AND PHYSIOLOGY

CHAIRMAN, DR. HARRY J. CORPER, OF DENVER.
SECRETARY, DR. JOSIAH J. MOORE, OF CHICAGO.

Absorption from the Lower Respiratory Tract Under Normal and Pathological Conditions.—Dr. H. J. Corper, of Denver, Col., said that absorption and resorption of liquids from the lower respiratory tract, the lungs and pleura, followed the main principles of absorption in other parts of the human economy, but the anatomical structure and physiological function lend to these tissues differences which are still to be determined. The rapidity of absorption of crystalloids from the lungs and pleura exceeded that from the peritoneum and subcutaneous tissues. Absorption of crystalloids was more rapid from the lungs than from the pleura and it was possible that absorption from the lungs in part accounted for the rapidity of absorption from the pleura. The rapidity of absorption of liquids from the lungs was probably to a great extent accounted for by the vascularity and large total surface of the terminal respiratory divisions—the alveoli. The absorption of crystalloids by the pleura was not influenced by artificial pneumothorax instituted shortly before and resulting in a decided collapse of the lungs. Acute inflammatory conditions affecting the pleura, produced by chemical means, retarded the absorption of crystalloids from the pleura. Acute inflammatory conditions affecting the pulmonary parenchyma retarded the absorption of crystalloids from the lung after intratracheal injection.

Grading of Carcinoma and Its Practical Application.—Dr. Albert C. Broders, of Rochester, Minn., said that carcinoma was graded by cell dif-

ferentiation, that process closely related to evolution by which cells advance from an immature to a mature or specialized state, or acquire a distinct and separate character. By comparing differentiated and undifferentiated cells of a malignant growth the malignancy may be properly graded on a basis of one to four. Grade one represents the most differentiated and the least malignant, and grade four the least differentiated and the most malignant. Other things being equal, about ninety per cent. good results may be expected in cases graded one; sixty per cent. in cases graded two; twenty-five per cent. in cases graded three; and ten per cent. in cases graded four. There was practically never metastasis from malignant tumors graded one, while the large majority of those graded four have metastasized by the time they reached the examining physician.

SECTION ON PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH

CHAIRMAN, DR. MATTHIAS NICOLL, JR., OF ALBANY.
SECRETARY, DR. W. F. DRAPER, OF WASHINGTON, D. C.

Is Trachoma a Deficiency Disease?—Dr. B. Franklin Royer, medical director of the National Committee for the Prevention of Blindness, said that trachoma usually began with an upper lid pathology, with bulbar infections developing secondarily from the traumatism. The disease was slow in progress and advanced by stages over a period of years. Spontaneous cure might often result. With unfavorable conditions, serious consequences might require prolonged treatment or cosmetic surgery. In the later stages severe suffering was noted, and serious impairment of vision or blindness might result. Geographically, the disease was not a problem except with people seasonally or habitually underfed. Public health authorities heretofore had overvalued governmental declarations stating that trachoma was a "dangerous infectious disease." Few reports of contagiousness or of transmissibility could be found in the literature that did not include the possibilities of transmitting many sorts of infections continuously associated in the trachomatous eye.

Modern studies to determine etiology should undoubtedly heed the lessons of research chemists determining conditions permitting deficiency diseases to develop. Epidemiological studies and etiological studies, Dr. Royer said, had so far been barren of results. New studies were needed which should include exact details of food habits in trachomatous families, both among the afflicted and in those escaping the disease, several years prior to and coincident with the first manifestations of eye trouble. Researches were needed comparable to those in producing xerophthalmia, but perhaps supplemented, short of this serious condition, by anticipating lowered resistance in lid tissues, and then, instead of carrying tissue change on further by withholding the essential element of food, to begin regular systematic irritation over long periods of time, concentrating the irritation upon the upper lid lining to determine if a pathology comparable to trachoma might be developed. Trachoma, he said, was a great international scourge and should be a challenge to the great foundations interested in international health problems.

SECTION ON UROLOGY

CHAIRMAN, DR. B. A. THOMAS, OF PHILADELPHIA.
SECRETARY, DR. GEORGE GILBERT SMITH, OF BOSTON.

The Pyelographic Diagnosis of Renal and Pararenal Neoplasms.—Daniel N. Eisendrath and Irvin S. Koll, of Chicago, said they believed ureteropyelography to be almost indispensable in the differential diagnosis of renal and pararenal neoplasms from those arising from intraperitoneal structures. There were certain pyelographic changes which were of unquestioned value in the diagnosis of renal neoplasms and polycystic disease. To these deformities the terms dragon, spider, etc., had been applied. The presence of a filling defect was equally as typical of neoplasm if one could exclude the presence in the renal pelvis of blood clots, fibrinous exudate, etc.

Deviation of the ureteral (opaque) catheter or of the ureterogram was found in both pararenal and intrarenal neoplasms. In pararenal (retroperitoneal sarcomata, cysts, etc.) there was no change in the contour of the pyelogram but the latter might reveal evidences of rotation or displacement of the kidney. In intrarenal neoplasms, on the other hand, there were always pyelographic changes in addition to the ureteral displacement. Familiarity with the many variations in normal pyelograms, especially of the socalled pseudospider type, was essential in order to avoid errors in pyelographic interpretation. Certain inflammatory (nonmalignant) conditions either of the fatty capsule (suppurative or fibrous perinephritis) or of the parenchyma of the kidney (atrophic pyelonephritis, tuberculosis) might give rise to pyelographic changes greatly resembling those of neoplasms.

Diagnosis of Renal Tuberculosis.—Dr. William E. Stevens, of San Francisco, said that notwithstanding tuberculous infection of the kidney the urine contained no tubercle bacilli in the early stage of the closed parenchymatous type of renal tuberculosis; it did later when the involved ureter was occluded. Tuberculosis of the kidney frequently occurred without symptoms in the presence of pulmonary tuberculosis. The author quoted statistics. He said tubercle bacilli were sometimes found in the urine in the absence of renal involvement. In the case reports it was pointed out that tuberculosis of the male genital organs was sometimes responsible for tubercle bacilli in the bladder urine. Renal and genital tuberculosis were frequently associated in the male but not in the female. In the absence of tubercle bacilli in the urine the diagnosis was at times difficult in those cases presenting symptoms also characteristic of nonrenal infection. The author said that the diagnosis was confirmed at operation in ninety per cent. of his cases with a positive guinea pig test. Tubercle bacilli were found in the smears in eighty-three per cent. of the specimens of urine from kidneys which he found to be tuberculous at operation. Lowenstein's study of various strains of tubercle bacilli showed some to be pathogenic for man but not for guinea pigs, and vice versa. Other means of diagnosis were palpation of the ureter through the vagina in women and the rectum in men. Catheterization through the Kelly cystoscope succeeded at times when other methods failed. Ureters were located following injection of indigo carmine if there was no marked decrease in renal

function. The author spoke of the liability of error following exploratory incision of kidney for diagnosis. He said the examination of urine obtained through incision of kidney pelvis or ureter was of greater value. Subcutaneous injection of tuberculin was suggestive in the presence of a focal reaction. This procedure was occasionally of value when the ureter was occluded, also when there was a question of bilateral infection. Cases were reported and the author stated that functional kidney tests were of little diagnostic value in the early stages of renal tuberculosis. There were bladder changes in tuberculosis of the kidney. Tuberculous calcification was frequent and a valuable diagnostic sign, especially when the ureter was closed and in bilateral infection. The classification of tuberculous shadows was taken up and illustrated by lantern slides and case reports. The differential diagnosis between tuberculous calcification and stones in the kidney was noted. The author said he had obtained the data by pyelography. He discussed the matter of putty kidney. It was also stated that tuberculosis of the kidney in children, according to statistics, was uncommon under ten years of age but actually more frequent than generally appreciated, and was often associated with pulmonary tuberculosis. The same diagnostic measures as those used in adults were indicated in children and infants, and he reported on the case of a child with tuberculous calcification in both kidneys, left ureter and bladder. The author further stated that tuberculosis of the kidney during pregnancy was uncommon but probably often overlooked. Lantern slides were used to demonstrate the principal points.

SECTION ON SURGERY, GENERAL AND ABDOMINAL

CHAIRMAN, DR. DALLAS B. PHEMISTER, OF CHICAGO.
SECRETARY, DR. J. TATE MASON, OF SEATTLE.

Recognition of the Patient Unsuited to Thyroidectomy in Exophthalmic Goitre.—Dr. William Bartlett, of St. Louis, Mo., emphasized the following symptoms in the diagnosis of exophthalmic goitre: Characteristic eye signs; thrills and bruits; vasomotor symptoms, such as vomiting, diarrhea, and sweating; nervous irritability; mental aberrations (of primary nature); crises and remissions. The patients generally unsuited to operation showed definite heart damage; increased blood nitrogen; high metabolic rate (40 plus); great loss of weight; absence of self-control; lowered blood pressure. The following circulatory conditions also rendered the patient unsuitable for operation: Temporarily, a heart temporarily exhausted; weak first sound; diastolic shading; ten day rest, no digitalis. Indefinitely, congestive heart failure; fibrillation, extreme shading; digitalis S. T. forty-eight c. c. in eight days; complete repair possible. Permanently, burned out. The types of patients unsuited to operation were: the fulminating type; adolescent patients; those with psychoses, epileptics; those sensitive to oxygen deficiency (often discovered at operation).

Direct measures used in preparing the patient for thyroidectomy were: Correction of thyroid secretion by means of Lugol's solution; decrease thyroid activity; restore nutritional balance; favor circulatory restitution; aid neuropsychic improvement. Indirect general measures included thyroidectomy; direct local measures included ligations, injections and radiation; indirect local measures related to the teeth, tonsils and sinuses.

Preparation was impossible in the following cases: Death from thyrotoxicosis; case dismissed as hopeless; patient intolerant of restraint; the presence of intercurrent diseases, such as pneumonia, scarlet fever, measles, postnasal infection or parotid abscess.

The patient was ready for operation when the heart condition was satisfactory (transient fibrillation); blood nitrogen under 50; metabolic rate under 40 plus; weight regained fifty per cent. of loss; selfcontrol reestablished; blood pressure 140/65-55 (all figures approximate).

Thyroidectomy was never an emergency procedure; it was better to await a maximum improvement.

SECTION ON DISEASES OF CHILDREN

CHAIRMAN, DR. CLIFFORD G. GRULEE, OF CHICAGO.
SECRETARY, DR. HUGH MC CULLOCH, OF ST. LOUIS.

Breast Feeding Problem.—Dr. C. Ulysses Moore, of Portland, Ore., presented a paper on problems in breast feeding. He touched upon the following points:

1. Reasons for breast feeding. 2. Problems: a. insufficient milk, 1, types of breast, and 2, improper stimulation; b. nipples, 1, hypertonic, 2, inverted; c. breasts, 1, caked, 2, mastitis, and 3, cancer complex; d. constitutional disease, 1, contagious, 2, heart, 3, kidney, 4, tuberculosis, 5, insanity; e. mental hazards; f. hygiene; g. nutrition. 3. Treatment and results in typical cases: a. manual stimulation in various types of improperly functioning breasts; b. use of nipple areators in pathological conditions of nipple.

In summing up, Dr. Moore said he might add that any mother who can care for her baby can nurse it, and that mothers who would nurse their young are often prevented by the mental hazards received directly or indirectly from the manufacturers of baby foods.

Letters to the Editor.

THE EFFECT OF OPERATION PER SE

NEW YORK, *May 27, 1926.*

To the Editor:

The writer has made futile efforts to get on the track of a paper written about 1895 to 1900 by Dr. John A. Wyeth, of New York, the former president of the New York Academy of Medicine, on "The Effect of Operation per se." In it the author referred—as far as I remember—among other matters to the spontaneous regression of carcinoma of the stomach, etc., after laparotomy. The exact title of the paper has slipped my memory, but I recall that it ended with the words "per se."

Dr. Wyeth is dead, and so are many of his former personal assistants. The medical libraries have been appealed to in vain. Yet, I am sure I saw the article in print.

It occurred to me to write you about it, in the hope that through your courteous intervention perhaps some hidden source might be uncovered, from which the lost paper would come to light.

WILLY MEYER.
700 MADISON AVENUE.

Abstracts from Current Literature

CARDIOLOGY

Efficiency of the Heart and Its Measurement.—Yandell Henderson (*Lancet,* December 19, 1925) states that the only adequate expression of the efficiency of the heart is one based on accurate measurements of the volume of blood that the heart pumps and upon the amount of oxygen consumed by the body. The relation between these two functions determines the arteriovenous oxygen difference, and thus determines the amount, and particularly the pressure of the oxygen supply to the working tissues of the body. In vigorous mammals of all sizes the arteriovenous oxygen difference during bodily rest is about three or four volumes per cent.

The volume of the circulation in vigorous men and animals at rest is about three to four litres of blood per minute per square metre of skin surface. The stroke volume for animals and men of corresponding activity is a function of their body weights not of their surfaces. For all vigorous mammals, including man, the stroke index during rest is about 1.4 to 1.8 c.c. per kilo per beat. The pulse rate is in general proportional to the surface weight ratio and is thus in general an index of the intensity of respiratory metabolism.

The mechanical conditions of the heart's activity and its own behavior make the right ventricle the meter of the circulation. The size of the stroke of this meter depends on the volume and pressure of the venous return. The venous pressure mechanism is adjusted to act in relation to the intensity of the gaseous exchange of the tissues.

Treatment of the Unusual Manifestations of Heart Disease.—The following lines of treatment are recommended by George R. Herrmann, (*Medical Clinics of North America,* January, 1926):

In coronary spasm or thrombosis immediate complete and continued rest in bed under morphine is indicated. Vasodilators are in order as soon as coronary spasm or thrombosis is suspected. Amyl nitrite, three to five minims, usually in pearls, should be administered by inhalations; nitroglycerin spirits, one to two minims, or one tablet, 0.0005 gm., given under the tongue, and erythrol tetranitrate tablet, 0.05 gm., every two or three hours.

Euphyllin (theophyllin ethylenediamin) is a most promising drug because it distinctly increases the coronary flow. It is given in 0.48 gm. doses two to four times a day. In urgent cases it is given well diluted intravenously, from specially prepared ampoules, or intramuscularly in a more concentrated solution, or per os in tabloid form, or per rectum in suppositories.

Benzyl succinate, 0.4 gm., two or three times a day, will often relieve and ward off minor coronary angiospasms and can be used over long periods of time.

Iodides and mercury have long been in use in cases where syphilis is the etiological factor, and often also where involutionary arteriosclerosis is the only recognizable basis of the symptoms. Where conduction defects are shown by the electrocardiogram, it is safer to use sodium rather than potassium salts. Since arsphenamine is also poorly tolerated in cardiovascular lues, the use of bismuth salicylate, 0.3 gm., injected intramuscularly every five days, seems to be the most rational treatment.

In heart block with Adams-Stokes attacks and with acute liver engorgement barium chloride in 0.03 to 0.05 gm. doses every three hours has proved most satisfactory in bringing a patient out of a stormy series of attacks and putting him back on his feet.

When increased vagus tone is responsible for the block, atropine sulphate 0.0006 gm., given every three hours or less frequently will keep the vagus pretty well paralyzed. Sometimes, however, the increase in auricular rate following atropine increases the degree of block. Electrocardiograms enable one to treat these patients most intelligently.

In paroxysmal auricular fibrillation, where the acute rhythm disturbance is threatening the life of a patient and where acute abdominal symptoms are presenting, it is not unduly heroic therapeutics to use quinidin sulphate. The drug can be given well diluted in doses of 0.13 to 0.19 gm. intravenously without much, if any, more danger and with much more definite results than when given by mouth in doses of twice the size at six hour intervals. The test for idiosyncrasy with a small dose, 0.065 to 0.13 gm. by mouth, should be carried out, or one tenth this amount by vein should be tried whenever the case is not too urgent.

In the more chronic types of heart failure prompt and complete digitalization is indicated whether auricular fibrillation or normal mechanism is present. In cases with delayed conduction atropinization will, as a rule, allow digitalization without blocking. Venesection, with the withdrawal of 500 c.c. of blood, will often relieve a greatly embarrassed heart and a congested vascular system and initiate a period of progressive improvement. Valvular lesions and congenital lesions, as mitral stenosis and defective interventricular septum, with great pulmonary congestion, are greatly relieved by bleeding. Not infrequently spontaneous hemorrhages serve to tide the patient along.

Aneurysms usually do not respond very favorably to antiluetic treatment, especially when they have reached the point of producing pressure symptoms. At times the rapidity of the progress of the lesion may be checked. Surgical wiring and electrocoagulation occasionally yield favorable results. Intrathoracic arterial and cardiac surgery is, however, still in its infancy.

Infections, pericarditis, and endocarditis do not respond uniformly to treatment. Salicylates in large doses, two grains to the pound of body weight per day, is about as effective as any remedy. In some cases organic dyestuffs injected intravenously have proved effective. Favorable results have been reported with sodium cacodylate injections. No specific medication has been discovered as yet. The complications of the infections must be treated more or less symptomatically. The severe anemia and uremia do not respond to the ordinary therapeutic procedures and the prognosis is, as a rule, hopeless.

Quinidin—A Useful Cardiac Remedy.—Robert L. Levy (*Medical Clinics of North America,* November, 1925) classifies his cases into those suitable and those unsuitable for quinidin therapy. Not every patient with persistent auricular fibrillation should receive quinidin, for two reasons. First, not every case will revert to normal mechanism, nor, if restoration is made, will this mechanism necessarily be maintained; second, by selection of cases, the danger of accident, chiefly embolism and sudden collapse, may be minimized. The chief criterion of the likelihood of a successful issue is the existence of a competent myocardium.

The suitable cases include: 1, fibrillation of recent onset; 2, little cardiac enlargement; 3, no valvular disease; 4, fibrillation associated with hyperthyroidism, provided there is only moderate myocardial damage.

The unsuitable cases are: 1, badly damaged hearts, especially those with marked hypertrophy and longstanding valvular disease; 2, hearts which after rest and proper digitalis therapy, evince but little evidence of restoration of reserve; 3, history of embolism; 4, acute or subacute bacterial endocarditis; 5, patients with an idiosyncrasy for cinchona derivatives; 6, occasionally, patients giving a history of cardiac pain which has ceased after the onset of fibrillation. It is emphasized that the number of patients suitable for the restoration experiment is distinctly limited. When in doubt, it is usually wiser to counsel against the use of quinidin and to employ the more conservative method of digitalis medication.

Proper preparation of the patient before beginning quinidin treatment is important. The patient should be in bed, under the supervision of a nurse, preferably in a hospital where electrocardiograms may be made if necessary. Heart failure, if present, must first be managed by rest, diet, regulation of fluid intake and the exhibition of digitalis. The ventricular rate should be maintained between sixty and seventy beats a minute, with the patient in bed. It is desirable to attain a maximal degree of circulatory efficiency. The individual doses of quinidin sulphate, in capsule form, are given at intervals of two hours as follows: First day, two doses of 0.2 gm. These are given to test for the presence of idiosyncrasy to cinchona. If this is found to exist, treatment must be abandoned. Second day, three doses of 0.4 gm. Third day, four doses of 0.4 gm. Fourth and succeeding days, five doses of 0.4 gm. The treatment may be continued for a week. It is safer not to give more than 2 gm. in twenty-four hours. The onset of frequent extra-

systoles or of persistently high ventricular rate affords an indication for cessation of therapy. If one course is unsuccessful, a second may achieve the desired result. Usually, however, a successful issue is attained in four to six days. If it is necessary to prolong treatment beyond this period, normal rhythm, even though restored, is often not maintained. The onset of persistent auricular flutter following quinidin is not of favorable import. Further doses rarely convert the flutter to normal rhythm under these circumstances. It is best to stop the quinidin and administer digitalis, following which a reversion to fibrillation almost invariably ensues. After the restoration of normal rhythm, it is probably desirable to continue with the use of small, daily doses of quinidin for several weeks. The administration of 0.2 gm. morning and evening usually suffices. This amount may be taken over long periods without danger.

The majority of patients with auricular fibrillation are aware of the irregularity because of palpitation. In order to maintain a relatively slow ventricular rate, constant digitalis medication is necessary. The response of the heart to effort is limited because tachycardia is readily induced. The author believes that the abolition of fibrillation is distinctly worth while, provided the limitations of treatment are observed and cases are carefully selected. The permanency of normal rhythm after quinidin is variable. Selected cases have not yet been followed long enough to venture a final estimate. Certainly the result often justifies the procedure. The patient is better because his symptoms are relieved; he is freed from the necessity of continuous digitalis medication; the response of the heart to effort is more effective; and he knows that his heart is beating regularly.

Quinidin has also been employed as a prophylactic in the attempt to prevent or reduce the incidence of attacks of paroxysmal tachycardia, both of auricular and ventricular origin. The results have been variable, depending in a measure on the associated cardiac condition. Similarly, premature beats, when annoying to the patient, may sometimes be abolished by small doses of quinidin. Quinin will often accompuish the same result. Experience with quinidin therapy of these forms of irregularity is still meager.

Prognosis and Treatment of Hypertensive Cardiovascular Renal Disease.—Elsworth S. Smith (*Medical Clinics of North America,* July, 1925) applies the term hypertensive cardiovascular renal disease to organic lesions of the heart, arteries, and kidneys resulting either primarily from essential arterial hypertension, or from an antecedent nephritis.

The prognosis in this class of cases is absolutely dependent on at how early a date the disease can be recognized and an intelligent prophylaxis instituted for the protection and salvation of the cardiovascular renal system. Hence the urgent need of routine blood pressure observations, especially at or about middle life. This question involves a consideration of all the known causes of arterial hypertension and their possible elimination, control, or amelioration, and then at the outset, from the viewpoint of prognosis, prophylaxis, and treatment should the subject of the affection under consideration be divided into two main causes.

First, into the renal and nonrenal groups, the former comprising the cases in which the disease has developed secondary to a primary nephritis, while in the latter group, sclerotic nephritis, when present, has developed secondarily to the arteriosclerotic process, the primary cause having been the accumulation of pressure substances in the blood. The latter is, by far, the larger group and constitutes the socalled hypertension or hyperpiesis of Allbutt.

Second, those still retaining, and those having lost their vasomotor response. For, in the first class, the serious and oftentimes fatal results may be altogether prevented or greatly retarded, while in the second group life expectancy is short at best, and the main reliance must be on the maintaining of the integrity of the propelling force of the heart.

In the renal type, showing a history of preexisting renal disease and evidence of marked renal insufficiency (low phthalein test and high nonprotein blood nitrogen), the prognosis depends, first, on the character and grade of the nephritis and the secondary effects of the hypertension on the heart and the arteries. The treatment also must include that of the existing nephritis through a low protein diet, largely of the Karrell type, a salt free diet when edema is present, and elimination by the emunctories and attention to complications.

In socalled essential hypertension, the several causes of hypertension require consideration, such as the possible causes of mental and physical wear and tear; foci of infection in the tonsils, nasal sinuses, the teeth, the appendix, gallbladder and the genitourinary organs; intoxications from alcohol, tobacco, coffee, tea, and industrial intoxications; Autointoxications; metabolic and endocrine influences; diabetes mellitus.

In such complications as cerebral hemorrhage and angina pectoris, the vasodilator remedies find their main indication. These are amyl nitrite, nitroglycerine, sodium nitrite, erythrol tetranitrate, and benzyl benzoate. The effects of the first two are very evanescent and doses must be repeated at short intervals. In uremic convulsions or coma, free venesection of at least sixteen ounces is indicated, replacing this amount with an equal amount of normal saline solution, or with ten per cent glucose solution if acidosis is present, together with insulin if indicated.

In the terminal stages, resembling the clinical picture of chronic cardiac decompensation from valvular disease, and if the symptoms are not too urgent or critical, an absolute rest on a strict Karrell diet is indicated. In more urgent cases a massive dose of digitalis will cause diuresis and marked improvement. The socalled theobromin group of diuretics are also valuable, especially agurin. The Nauheim or Schott baths and resistant movements also act well in selected cases, but should be carefully administered.

Digitalis Hypersusceptibility and Digitalis Dose.—Walter A. Bastedo (*Medical Clinics of North America,* November, 1925) summarizes the proper methods of dose and administration as follows:

1. Digitalis effects may be obtained very quickly by mouth administration.

2. When full digitalis effects are desired, as in auricular fibrillation cases, the patient should be in bed and watched.

3. The drug should be stopped at the first toxic indication, for overdoses are harmful and their effects may not be readily recovered from.

4. Digitalis hypersusceptibility is encountered in a sufficient number of cases to make it of moment. For the nonurgent auricular fibrillation or flutter cases either, 1, a modification of Eggleston's method is recommended as follows: Having calculated the total average required dose on the basis of 0.15 c.c. of the tincture per pound of body weight, give one quarter of this calculated amount at once. and thereafter one eighth every six hours till the desired effect is obtained or some evidence of digitalization becomes manifest; or, 2, since busy doctors resent the need of exact figuring, give one dram of the tincture at once, and then 0.5 dram every six hours till digitalization is evident. For digitalis powder use one tenth of these amounts in gram or grain. For the infusion use seven times as much in cubic centimeters or minims. The same doses are applicable in fever cases, such as pneumonia. In normal rhythm cases much smaller doses usually suffice.

5. Till digitalization is obtained watch with the utmost care for the first signs of overdoses. In hypersusceptible cases these will appear early. In the resistant cases the doses may be increased as soon as it is evident that effects are not being obtained.

6. Use digitalis with great caution in patients who have been taking the drug within three weeks.

7. Do not attempt to digitalize an ambulatory (office) patient. For such, however, small doses may be valuable, either of themselves or to continue a state of digitalization previously brought about.

8. To obtain effects in normal rhythm cases it is rarely necessary to digitalize fully.

9. Intramuscular administration is called for only if the stomach is intolerant from other than digitalis causes. However, it is to be borne in mind that a sensitive stomach may very early become intolerant to digitalis, i.e., before the patient is digitalized, and that a patient with such a stomach can be digitalized by the hypodermic method. Or administration by mouth may be prevented by the persistent vomiting associated with decompensation so that hypodermic doses are indicated.

10. Intravenous adminstration of digitalis is especially dangerous and is unecessary. If the intravenous route is selected strophanthin should be preferred.

11. After digitalization is accomplished the effect may usually be maintained by twenty or thirty minims a day, but sometimes by as little as two, three, or five minims a day.

Safety lies in stopping digitalis altogether or in materially reducing its dose when

1. Digitalization is shown by the electrocardiograph.
2. The desired effect is accomplished, as by the disappearance of dropsy or enlargement of the liver, or by the slowing and steadying of the pulse in auricular fibrillation.
3. Nausea is marked or vomiting ensues. An exception is mentioned in the previous section, paragraph 9.
4. The patient complains of headache, anorexia and dizziness, or lightheadedness.
5. The cardiac rate goes below 60. The heart may become progressively slower for several days after the drug is stopped, hence the wisdom of ceasing the administration before the slowing has become extreme.
6. The rate slows suddenly.
7. Coupled rhythm appears.
8. Premature beats occur.
9. A regular rhythm becomes irregular or intermittent.
10. Sinus arrhythmia appears in normal rhythm cases or phasic arrhythmia in auricular fibrillation cases.

Clinical Aspects of Ischemic Necrosis of the Heart Muscle.—Alexander George Gibson (*Lancet,* December 19, 1925) remarks that the first requisite in the detection of ischemic necrosis of the heart muscle is a clear knowledge of the anatomical process, and to have it in mind in approaching a cardiac case in any person over forty years of age. We ought, he thinks to be secretely ashamed if we are reduced to diagnose mitral regurgitation or cardiac dilatation or even auricular fibrillation without a hint of etiology. We are most likely to be right in a diagnosis of ischemic necrosis in angina if we take care to exclude certain obvious possibilities such as aneurysm. Chronic cardiac failure in old people in the absence of syphilis, old rheumatic affections of the heart, and pernicious anemia, is almost certainly due to ischemic necrosis. Chronic cardiac failure plus evidence of aseptic embolism makes the diagnosis of ischemic necrosis practically certain.

The pulse gives help occasionally. Mackenzie has noticed in two of his cases pulsus alternans one of the author's cases had fibrillation, another, at the time of the initial lesion, irregularity in rhythm and volume probably due to fibrillation. The pulse has been recorded both fast and slow. The pulse, therefore, may give some import of cardiac failure, but can give nothing else.

The first sound of the heart is frequently poor in quality or even absent. The electrocardiogram has been explored as a means of getting greater accuracy.

The Cardiac Reserve.—T. L. Deaver (*American Journal of Surgery,* September, 1925) states that: The cardiac reserve is an accessory power, present to a certain degree in every individual, but greater in some than in others, and is capable of being dissipated or conserved.

Being a latent power, so to speak, it is called upon only in emergency, and is the all important element in recovery from any surgical operation.

It is a power dependent, to some extent, upon extracardiac influence, especially that of the central and sympathetic nervous systems and the glands of internal secretion, but resides largely within the mechanism of the heart. Though tenacious in quality, it is profoundly affected by shock from any cause. It may be suddenly terminated by grave injury to the head, chest or abdomen, or gradually subdued by hemorrhage, by disease or the changes incident to old age.

The amount of cardiac reserve should be determined, as nearly as possible, in every patient who is to be subjected to major surgery. A complete physical examination, a well taken history, the usual analyses, the electrocardiograph, blood pressure, the metabolic rate and roentgenography, with special study of the pulse, both at rest and after exertion, are the more substantial means at our command. Great importance is attached to the correct interpretation of these findings. Even then, we cannot always estimate the strength of the heart muscle, and therefore of the cardiac reserve, since the limitations of physical life are more or less fixed by conditions over which we have no control.

Suspension of the cardiac reserve is not always fatal, for many persons have been restored to life by means of the pulmotor, massage of the heart and by injections of adrenalin chloride directly into the heart muscle, even when death seemed inevitable. When the cardiac reserve is exhausted, however, nothing known to science can again set in motion the machinery called life.

Sudden Death Due to Exacerbation of Latent Syphilitic Myocarditis.—Aldred Scott Warthin (*American Journal of Syphilis,* January, 1926) reports eight cases to show that sudden death may occur in latent syphilis as the result of an acute exacerbation of previously mild, latent processes in the heart and aorta. The pathological character of the active lesions differs from that of the chronic lesions in the more marked edema and the greater polymorphonuclear cell content of the infiltrations. Very acute and active syphilis is characterized by more diffuse lesions, more marked edema and a greater number of polymorphonuclear cells in the infiltration. The typical picture of perivascular lymphocyte and plasma cell infiltration and eventually fibrosis will, however, always be associated with these when the active process is an exacerbation of an older latent syphilis. The polymorphonuclear infiltration of the critical reaction is believed by some to be just as typical for syphilis as is the focal round cell infiltration for the chronic type of syphilitic process. This fact may not be recognized by the pathologist who carries in his mind the mononuclear type of infiltration as the characteristic diagnostic picture of syphilis, and he may, therefore, fail to recognize the polymorphonuclear malignant type of syphilis. At any rate, the demonstration of the spirochete in the latter type of lesion is the only decisive diagnostic point, and must be accomplished to fix the diagnosis, and unless this is done such cases will escape proper interpretation. Unfortunately for the recognition of these cases, in how many pathological laboratories are routine examinations for spirochetes made?

The factors leading to such an increase of virulency in chronic latent cases are still unknown, beyond the vague conception of lower resistance due to overstrain, fatigue, other infections and intoxications, endocrine changes, other environmental influences, etc.

Much is being said at the present time as to the great frequency and apparent increase of cardiac disease, but the important if not predominant rôle played by syphilis in the production of myocardial incompetency is not recognized by the major part of the profession.

Socalled cardiac failure as a result of syphilis may be brought about in several ways:

1. Myocardial atrophy and fibrosis due to slowly progressive mild syphilitic lesions in the myocardium. This is the most common form.
2. Syphilitic disease of the coronaries with resulting infarction and fibrosis.
3. Combination of these two processes.
4. Syphilis of the aortive valve. Always associated with some degree of myocardial syphilis.
5. Combination of myocardial syphilis and syphilitic mesaortitis.
6. Acute exacerbations of a previously latent syphilis (critical stage of syphilitic infection) or an acute malignant type of cardiac syphilis. This is much less common than the chronic latent form, but its frequency remains to be determined, as it has not received pathological recognition.

New Clinical Points of View in Cardiac Asthma.—As the result of his very intensive clinical study of cardiac asthma, Sigmund Wassermann (*Wiener Archiv für innere Medizin,* January 5, 1926) draws the following conclusions:

Asthmatic attacks occur in insufficiency of the left as well as of the right heart. The former represent the typical cardiac asthma, the classical form of heart asthma, the latter more the asthmatoform attacks. Typical cardiac asthma is the acute variety of the dyspnea of the greater circulation or spontaneous dyspnea.

Pathogenetically, it depends on a functional insufficiency of the left ventricle and its normal effect on, a, the arterial circulation (somatic) and b, the central nervous system in the sense of a dyspneic anoxemic stimulation. Liability of the left ventricle is a purely functional conception and has nothing to do with real insufficiency—actual failure and retrograde, i.e., pulmonary stasis.

Pathophysiologically, cardiac asthma is the reaction of the central nervous system, especially the medulla oblongata, upon the (cardio) arterial sector of the dyspneic stimuli originating in the greater circulation, and has the significance of a sudden protective reaction and mechanism against a choking that originates and appears centrally. Dyspneic irritations resulting from pulmonary stasis have

thing to do with this reaction primarily. All of the cen- ally produced reactions represent the cardioasthmatic syn- rome and consist of a double series of (subjective and ob- ctive) signs of disease.

The subjective symptoms are the adequate psychic cor- elative of the arterial anoxemic choking and includes the roup of centrally precipitated symptoms of air or oxygen unger: a, the motor and psychomotor unrest, such as de- ire for movement, flight impulses, etc.; b, anxiety (res- iratory); c, oppression (respiratory angina); d, sensation f choking (suffocation); e, sensation of strangulation.

The objective symptomatology includes all the symptoms roduced by the dyspneic stimulation of the various bulbo- pinal centres; in the peripheral respiratory apparatus, the ardioasthmatic dyspnea; maximal, occasionally stormy espiratory activity with the use of the auxiliary respiratory nuscles. The breathing is mostly deep, and the frequency increased; in the vegetative nervous system with the omatic visceral signs in the lungs (bronchial constrictors, difficult expiration), in the heart (bradycardia, palpitation of the heart); in the pharyngeal gastrointestinal tract spasms of the pharyngoesophageal musculature—sensation of strangulation—nausea and other gastric symptoms, tenes- nus, etc.; in the bladder, strangury and frequent mic- turition; in the vasomotor centre: increased blood pres- sure, occasionally rapid and high.

Clinically, there is the aortic heart (large and small) and especially the insufficiency of the aortic valve and the in- farct of the left ventricle. The course of the disease may vary: 1, spontaneous recession; 2, exhaustion of the res- piratory centre, with Cheyne-Stokes or terminal asphyxia (paralysis); 3, cardiac insufficiency, with pulmonary con- gestion or edema.

The treatment includes the specially effective morphine or opiates, oxygen, and the vascular remedies, such as nitro- glycerin, etc.

In asthma of the lesser circulation, or congestive asthma, there are attacks of dyspnea with marked insufficiency of the circulation, namely, in the pulmonary and venous sector, with cyanosis, dyspnea (orthopnea) hydrops, etc. The symptoms include intense cyanosis, exaggeration of the ob- jective dyspnea, slight or no rise of blood pressure, and at- tacks of dyspnea in series. Clinically, we see the mitral heart or insufficiency of the right heart. The treatment in- cludes venesection, cardiac remedies (digitalis group, caf- feine), morphine in trial and in very small doses, and oxy- gen. The prognosis is extremely bad.

Portal Hypotension.—H. Surmont (*Bulletin de l'Académie de médecine,* January 12, 1926) calls attention to the clinical importance of the syndrome of portal hypotension, meaning by the latter a reduction in the quantity and pressure of blood in the portal vein. Acute portal hypotension is produced clinically by conditions that suddenly dry up the portal tributaries, such as obstinate vomiting and acute diarrhea. Chronic portal hypertension, much oftener over- looked because of its being latent, can nevertheless be daily detected by the observant physician and plays as important a part in stenoses of the upper portions of the alimentary canal as does portal hypertension in venous cirrhoses of the liver. The symptoms arising mechanically from portal hypotension are both abdominal and remote. Distally to the liver, the results are the same as in portal hypertension, viz., a small heart and pulse, low blood pressure, increased heart rate, reduced urinary output, sometimes albuminuria, dryness of the skin and mucous membranes, and loss of weight because of general dehydration. The loss of flesh from portal hypo- tension is pronounced and general, in contrast to that from portal hypertension, in which the emaciation of the body below the diaphragm is masked by edema of the lower limbs and ascites. In the liver itself, portal hypotension is marked by reduced size of the organ, which is made up, however, with abnormal rapidity through "avidity of the colon" upon proctoclysis. Proximally to the liver arise the most typical of the symptoms of portal hypotension, viz., emaciation, markedly scaphoid abdomen, diminished abdominal tone, pale and withered abdominal skin, gastric abnormity varying with the cause of the portal hypotension, a "wet rag" small in- testine, cordlike colon, and the anus free of hemorrhoids or with shrunken hemorrhoids. The diagnosis of portal hypo- tension is clinched by certain manifestations or tests demon- strating avidity of, i. e., unusually rapid absorption by the bowel. Avidity of the small intestine is shown by the ab- normal output of urine early in the night brought on by the recumbent position in patients with pyloric stenosis. The condition may be shown artificially by an induced urinary elimination test, carried out on different days, with the subject standing and reclining; care is taken to have the stomach empty before the tests. Avidity of the colon is demonstrated by an unusually rapid absorption of isotonic glucose solution, given at body temperature, from the bowel; this unusual rate is discerned not only through the increase of the body weight and diuresis, but also through a drop in the erythrocyte count and blood viscosity. The clinical significance of the study of portal hypotension lies in that it enables the obstetrician to combat early the conditions of dehydration and hepatic insufficiency which are at the bottom of the pernicious vomiting of pregnancy; use of the urine graduate and administration of glucose solution rectally in the daily amounts indicated will vastly improve the prognosis of these cases. The surgeon, on the other hand, should avail himself of "colonic avidity" in cases with stenoses of the upper portions of the alimentary canal to carry out a fundamental treatment of low blood pressure, restoring body heat, counteracting shock, reestablishing function of the underfed glands, and, in particular, reawakening with a direct supply of glucose the activity of the liver cells, with their glycogenic and antitoxic functions.

Congenital Cardiac Hypertrophy.—As congenital car- diac hypertrophy is sufficiently rare, A. J. Scott and A. H. Zeiler (*American Journal of Diseases of Children,* January, 1926) wish to record another case. The patient, a girl of five weeks, was referred because of gastrointestinal dis- turbance, dyspnea and cyanosis. At necropsy the heart was found to weigh 55.4 gm. (similar to that of an infant aged eighteen months) and was 6.5 cm. wide. There was marked hypertrophy of the ventricular musculature. The ductus Botalli and foramen ovale were closed, and all the valves were competent. The left auricle was normal in size, but the right was dilated. There was a slight increase in the pericardial fluid. The lungs had some hypostasis, and the thymus was normal in size for the age. The abdominal organs were normal except for the enlarged liver and passive congestion in the kidneys.

Coarctation of the Aorta.—An interesting point about a case of coarctation of the aorta of the congenital type re- ported by James W. Bruce and Robert Ball (*American Journal of Diseases of Children,* February, 1926) is the similarity of its clinical manifestations to those of intra- cranial injury caused by birth trauma. It seemed logical to the author to believe that marked narrowing of the lumen of the aorta distal to the great vessels supplying the head would cause increase of intracranial pressure. The diam- eter of the ascending arch of the aorta was seven mm. and it had diminished to four mm. just distal to the point of origin of the left subclavian artery, later widening to its original diameter before joining with the ductus arteriosus. The infant whose case is described lived forty hours. Its convulsions occurring at intervals of thirty minutes to two hours were limited to the face and upper extremities.

Operative Treatment of Angina Pectoris.—H. H. Kerr (*Annals of Surgery,* September, 1925) finds that the Ameri- can operation of resection of the superior cervical sympa- thetic ganglion under infiltration anesthesia affords a higher percentage of relief than the more difficult and dangerous operations in use. The only difficulty in this operation is the differentiation between the vagus with its bulb and the elon- gated sympathetic ganglia. This may be overcome by the knowledge that when the vagus nerve is grasped with smooth thumb forceps and gently squeezed the systolic blood pressure drops and, with the release of the nerve, the blood pressure resumes its former level. The pulse rate is not altered by this manipulation. Squeezing, or even tearing out the superior cervical ganglion, has no marked effect on the blood pressure. This phenomenon suggests that the de- pressor nerve is included in the vagus sheath at this level.

The author reports on eight patients, operated upon by him, remarking that none has since died of the disease as far as can yet be ascertained.

Development and Size of the Heart in Children.—Thomas Ziskin (*American Journal of Diseases of Children,* December, 1925) presents charts on the development and size of the heart in children as revealed by teleoröntgen ray measurements.

Medicolegal Notes.

WHETHER A MEDICAL COLLEGE IS A CHARITABLE INSTITUTION HELD A QUESTION OF FACT

A college of physicians and surgeons was organized under Massachusetts St. 1874, c. 375, as amended by St. 1875, c. 49, sec. 1, "an act concerning associations for religious, charitable, educational and other purposes" and was empowered under St. 1883, c. 153, to confer the degree of doctor of medicine. In an action in tort against the hospital for damages for the death of a patient alleged to have been caused by negligent medical care and treatment of the patient by the defendant's servants and agents or by the negligent administration of medicines, the Massachusetts Supreme Judicial Court holds, Hall v. College of Physicians and Surgeons, 149 N. E. 675, that the charter of the college did not of itself make the college a public charity. The controlling purpose must be for the common and public benefit, and if it was created by the incorporators, or thereafter was administered and maintained by their successors for money making, this essential element was lacking, even if it might at times have expended money for purposes, or rendered gratuitous services which in common speech are called charitable. The defendant still would be acting within its charter powers if it charged every student in full for tuition, and clinical patients for medical care and treatment.

REVOCATION OF LICENSE FOR PUBLISHING FALSE AND UNAUTHORIZED ADVERTISEMENT AS TO CURE

The Supreme Court of Colorado, Doran v. State Board of Medical Examiners, 240 Pac., 335, affirmed the judgment of the district court dismissing a writ of certiorari to review an order of the State Board revoking plaintiff's license on the ground of immoral, unprofessional and dishonorable conduct in causing an advertisement containing the untrue and unauthorized statement that he had professionally treated and cured a patient of ulcers of the stomach to be published for the purpose of misleading readers of the advertisement. The complaint had been filed with the state board by the person whose name had been used. The court said, in part: "The state board of medical examiners has been created by our General Assembly as an administrative body, and invested with power to protect the public health and to control and regulate the practice of medicine in this state. Among its powers are the granting and revoking of licenses to practice medicine in this state. A license that has been granted may be revoked if the holder is guilty of immoral, unprofessional, or dishonorable conduct. No one may lawfully practice medicine in this state without a license from the board or continue to practice after his license has been revoked. . . .

"Upon this board of medical examiners was conferred the power to pass upon such charges. Its jurisdiction to do so is unquestioned. There does not appear to have been any abuse of discretion on its part. The courts are not called upon in such a case to pass upon the weight or sufficiency of the testimony upon which the findings of the board are based. There certainly was testimony to sustain its findings. This and other courts have repeatedly held that the object of certiorari is not to settle or determine disputed facts, but to investigate and correct errors of law of jurisdictional nature, and, under the Code of Procedure, abuse of discretion. In the case of State Board of Medical Examiners v. Brown, 70 Colo., 116, 198 Pac., 274, we said that section 337 of our Code of Civil Procedure 1908 defines "abuse of discretion" as a failure by a tribunal regularly to pursue its authority, and that does not include the commission of mere errors of law or mistakes in the finding of facts.

"Since the medical board had jurisdiction both as to the subject matter of its inquiry and of the person of the plaintiff in error, and having, as the record shows, regularly pursued its authority, the district court was right in dismissing the writ of certiorari, and its judgment is therefore affirmed, and supersedeas denied."

CALIFORNIA CHIROPRACTIC ACT DOES NOT REPEAL SECTION 17 OF MEDICAL PRACTICE ACT AS TO UNLICENSED PERSONS

A person practising as a chiropractor without the license required by section 15 of the California Chiropractic Act may, it is held, People v. Mills, 240 Pac., 296, be prosecuted in the Superior Court for violation of section 17 of the Medical Practice Act as amended in 1917, for practising without a license, since, by the provisions of section 18 of the Chiropractic Act, no part of the Medical Practice Act is repealed, save and except as to those portions which are in conflict with the Chiropractic Act, when applied to persons holding a license issued by the chiropractic board.

Under the two acts, the District Court of Appeals, Third District, California, says, a complete defense to a charge of curing without a license is the introduction and showing by the defendant that he holds a license from either board. Prior to the adoption of the initiative act relating to chiropractors in 1922, it was unlawful to practice that system of curing without having obtained a certificate from the state medical board of examiners. That situation, however, has now been corrected, so that, if a defendant is charged under section 17 of the Medical Practice Act, and if it be found that he is following the system used by chiropractors, then his complete defense is the showing that he holds a certificate from the chiropractic board. In other words, section 17 of the Medical Practice Act is allowed to remain in full force and effect by the initiative measure known as the Chiropractic Act, to apply with full force and effect as fully and completely as it did prior to 1922 by the terms of section 18 of the Chiropractic Act, to all unlicensed persons.

It was held that there was no merit in the contention that the defendant was subject to different degrees of punishment in different courts by reason of the difference in the terms of the two acts; nor in the contention that the defendant had been improperly convicted under an act which applied to him, to wit, one not holding any license, simply because he might also have been prosecuted in another court, or in the justice's court, for the same act and a lesser possible penalty imposed. The fact that the defendant had violated both acts did not relieve him from prosecution under the Medical Practice Act, its provisions not having been repealed by the Chiropractic Act.

SUFFICIENT DEMAND FOR AUTOPSY UNDER ACCIDENT POLICY

The Ohio Supreme Court holds, Gath v. Travelers' Ins. Co. of Hartford, Conn., 149 N. E. 389, that where a clause in an accident insurance policy gave the insurer the "right and opportunity to make an autopsy in case of death," the demand for an autopsy to be seasonable, must be made before burial when the death is known to an agent of the insurer a reasonable time before burial, and he has grounds for believing death was caused by other than accidental means.

Where a widow living at the home is named as the sole beneficiary of the insured, under the opportunity clause of the policy such demand must be made upon her. Verbal requests for opportunity to make an autopsy, made by an agent upon the son before burial, are not sufficient, where the son unequivocally notifies the agent that he will not, and does not, communicate such requests to the beneficiary.

Good Faith With You!

The practicing physician has a right to expect that the remedies that seek his attention and patronage shall not be exploited to his patients. He—and he alone—is competent to treat the sick. Therefore, during the third of a century and more, that

Gray's Glycerine Tonic Comp.

(Formula Dr. John P. Gray)

has been serving the physicians of the country, it has never been advertised to the laity. In its manufacture, introduction and distribution, "*good faith with the medical profession*" has been the watchword.

Your card or letterhead will bring a regular 6-ounce bottle free of expense.

THE PURDUE FREDERICK CO.
135 Christopher St., New York

IT is easy to understand why Gray's Gycerine Tonic Comp. is today so widely used by discriminating practitioners. They know they can rely on its ethical standing no less than on its therapeutic efficiency.

Valentine's Meat-Juice

The **Power** of **Valentine's Meat-Juice** in **Quieting** the **Irritable Stomach, Aiding** the **Digestion, Restoring** the **Appetite** and **Sustaining** and **Strengthening** has been demonstrated by many **Medical Men** in the treatment of

Anaemia, Exhaustion *and* Debility.

Dr. R. Sarandeses, *Physician to the Provincial Hospital Oviedo, Spain:* "I had occasion to use VALENTINE'S MEAT-JUICE on a member of my own family and with excellent results. It is most agreeable to the sick and well, is easily prepared and administered, and for the young anæmic constitutes a superior remedy."

Dr. Lenoble, *Surgeon in Chief, Military Ward of the Hospital D'Argentan, Argentan, France:* "The powerful reconstituent, VALENTINE'S MEAT-JUICE, brought about a great improvement in the condition of the sick and wounded, whose long stay in the trenches had made them particularly anæmic."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Inoculation and Vaccination.—Dr. Edgard Le Roy tells us (*Æsculape,* May, 1925) that Marius, bishop of Avenches, recounts that in 570 and 580 an epidemic of *petite vérole* (the word appeared for the first time here) ravaged Saul and Italy. Two children of the royal family died. In 580 the wife of the King of Burgundy, stricken with the disease, and finding herself at the point of death at the age of thirty-two, asked of her husband a last favor, the death of her physicians, Nicholas and Donatus, whom she accused of having hastened her end with their medicines. Nicholas and Donatus were slaughtered on the tomb of this amiable lady. Eleven centuries later the royal family of France were again dramatically decimated by the same disease. The Duke of Burgundy, his wife, and oldest son died of variola.

Cures were very rare, but it seems that it had already been known for some time that a way to make smallpox less fatal was to "graft" it on the arm of the healthy. It was the wife of the ambassador from England to Constantinople, Lady Montague, who in a letter of April 1, 1717, was the first to speak familiarly of this curious method of protection against this terrible scourge. A curious method in truth, scandalous, even, to our confreres of that time, all of whose beliefs were upset and thrown awry by it; for it meant simply the giving of smallpox in a prophylactic way to a healthy person by grafting on his skin "sprouts" from a person suffering from the disease. Persons thus inoculated were very well until the eighth day; then a fever appeared; they had on their faces about twenty postules which never left marks; they stayed in bed two days, rarely three; in eight days more they were cured of the light, mild form of smallpox which they had voluntarily given themselves, in order to escape those afflicted with acute smallpox to whom one is always exposed during an epidemic.

This method of protection was called inoculation or insertion. Lady Montague devoted herself to propagating it in her country and throughout Europe, first by having her own son aged six vaccinated, then by multiplying her letters and her efforts. At first ignorance, envy, distrust, malevolence, leagued themselves together against the new method. Finally in 1721 the College of Physicians of London proposed experimenting with "insertion" on six persons condemned to death, four men and two women. All recovered and thus saved their lives. In 1722 the Princess of Galles had her two daughters and later her son inoculated. France herself was rather averse to receiving inoculation, a little, without doubt, because of a national hesitation in following a foreign custom. A religious issue was made out of its introduction, and a long time passed before the attitude toward it was other than hostile. Finally, thanks to the strenuous efforts of the Encyclopedists, Voltaire, and above all La Condamine, toward the end of the eighteenth century the new method became acclimatized in France. The kings had their children inoculated, favored its introduction into the provinces, and, if people still died of smallpox, there were certainly fewer deaths than at the beginning of the century.

The next important step was the discovery by Jenner of England that cattle suffered from cow pox, and his decision to try inoculation with vaccine from cows instead of from human beings. But the honest Jenner did not try out his theory until after twenty years had passed. When the method was found to be successful, a Central Institute of Vaccination was opened in London, and Parliament bestowed upon Jenner a recompense of twenty thousand pounds.

In France it was the Duke of La Rochefoucauld-Liancourt who undertook to propagate Jenner's method. In cooperation with the director of the School of Medicine of Paris he organized a sort of propaganda committee for the extension of vaccination, and in 1801 the government established a special hospital for inoculation of vaccine. The method became so widespread and so popular that by 1820 poems were being written on the subject.

In Germany it enlisted in the same way the enthusiasm of princes, the people, and the scientists, and also in Denmark. In Russia the dowager empress gave the name of Vaccinof and a life annuity to the first Russian infant vaccinated. In Turkey, on the banks of the Tigris and Euphrates, at Bombay, Ceylon, in Mysore, Malabar, everywhere, it was received with delight. Everywhere rejoiced over, everywhere acclaimed at once, a spectacle unique in all the history of medicine. At the same time vaccination reached the United States via England, and Jefferson, President, was vaccinated, together with eighteen members of his household. But not one of her contemporaries equalled the efforts of Spain for the propagation of vaccination. A scientific expedition was sent out by Charles IV to the Canaries, Porto Rico, the Antilles, Venezuela, Mexico, Peru, Bolivia, Chile, etc., with men and materials to vaccinate the poor and establish institutes of vaccination.

Such was the triumphal voyage of vaccination around the world. This method is so familiar to us today that it is hard to realize and appreciate its inestimable value and the obscure efforts, incalculable in number, of modest and devoted physicians. Smallpox has practically disappeared from our countries. How many young doctors have never seen it! In 1870-71 there were reported to be two hundred thousand cases in our armies. During the four years and a half of the World War there were only twenty-six.

The Le Roy Crummer Collection of Old Medical Books in Omaha, Nebraska.—The catalogue of this collection would delight a collector of rare books. It bears the title *A List of Old Medical Books on the History of Medicine, and Medical Bibliography, and a List of Medical Portraits,* and each entry not only gives the necessary bibliographical information, but fully describes the editions. Among them are works of Sir Thomas Browne, Coranaro, Celsus, Galen, John Gerson, William Harvey, Edward Jenner, Paracelsus, and Vesalius. The majority of the books belong to the sixteenth and seventeenth centuries, representative not only of the great era of charlatanism, but also of experimentation and advance in medical science.

THE VALUABLE MEDICINAL PROPERTIES

of Dr. Siegert's

ANGOSTURA BITTERS

(Elix. Ang. Amari Sgt.)

are established by the testimony of medical practice throughout the world for three generations. It has wide scope as a flavoring agent in prescriptions, and also as a tonic and direct stimulant of appetite and metabolism. For a complimentary sample and particulars write to

"Diabetes, Diabesan and a Grateful Patient"

Point Pleasant Beach, N. J.,
September 29, 1925.

Dr. Werner.
My dear Friend:—

I can call you friend as "Amicus certus in re incerta cernitur."

When I left the hospital last May after the "Allen Starvation Treatment" I weighed only 106 lbs., very weak and debilitated with glycosuria and glycemia, very much discouraged and melancholy. Dr. Shoub wrote me that he had seen very good results from the "Rational Treatment of Diabetes," by Dr. Werner, President of the Solosan Company of Morristown, N. J. With much misgiving I began your treatment about July last.

I want to congratulate you on my condition. I now weigh 122 lbs., very good color in my face, no sugar in the urine, very little blood sugar, no diacetic acid, no acetone.

I feel much stronger and do not tire easily, as before. I sleep better and not so nervous. I feel better and clinically proven to be better.

A grateful patient,
REV. JOSEPH V. SWEENEY.

Ingrafting of Hundred Years Ago.—The satirical humor of Butler threw an air of disbelief over the operation of ingrafting noses as performed by Taliacotius, but the following details taken from the German journals of 1825 show the efforts made by scientists to extend the scope of the Taliacotian idea. A certain Dr. Dieffenbach took feathers of various sorts from chickens, pigeons and sparrows and "dibbled" them with a trochar into the skins of rabbits, puppies and kittens, where they took root and grew. He then ingrafted successfully upon his own arm the hairs of a friend's eyebrow. A claw detached from the toe of a pigeon was ingrafted upon its tail, "this being the most wonderful experiment of all, for, though the claw did not itself take root in the tail, it seems to have deposited there the egg of a claw, and a very fine new claw sprouted out from the same place. The feather which had been plucked out to make room for the claw grew again, and an obstinate contest arose between the feather and the claw for priority of place, in which the feather at last succeeded in expelling the intruder."—*Medical Press.*

History of Smallpox.—Prefacing his article on Smallpox in Canada, Dr. J. J. Heagerty writes (*World's Health,* August, 1925) that the word *pox* comes from an old Saxon word, *pocca,* meaning a pouch or bag. There is in India a tradition that smallpox existed among the Brahmins since the beginning of time, and that the inhabitants of India built temples and shrines and offered sacrifices to the goddess of smallpox to grant them protection from the disease. Modern writers tell us that the disease existed in China a thousand years before Christianity, and that it was believed by the Chinese, as in India, that a goddess presided over the disease, and, like the Brahmins, the Chinese built temples and propitiated the goddess by sacrifices. It is probable that smallpox existed among the ancient Greeks and Romans, although the evidence is not conclusive.

In the early Christian era, the first mention made of the disease is by Bishop Marius of Lausanne in the fifth century. Writing in 570 A. D. he describes a vast epidemic that swept over Italy and France, and a few years later Bishop Gregory of Tours speaks of the disease. He says that it is characterized by fever, pain in the back, and an eruption of pustules most marked on the face, hands and feet. In the seventh century, the disease found its way into the British Isles.

The first clear description of smallpox was by a physician who was known as Isaac the Jew. He lived in the ninth century. Rhazes, an Arabian physician, was the first to point out the fact that smallpox was a disease of children. In the British Museum are manuscripts from the tenth and eleventh centuries describing smallpox. In one of these, known as the Harleian manuscript, there is a Saxon prayer, "shield me from the hideous pocks." In the thirteenth century John of Gaddesden recognized the contagiousness of the disease. In 1758 Cardinal Wolsey was informed that Henry VII was leaving Wallingford on account of the prevalence of "small pokkes."

That smallpox was no respecter of persons is shown by the long list of notables who died from the disease. Among them were William of Orange, Emperor Joseph I of Germany, Peter II, Emperor of Russia, Louis XV of France, two children of Charles I of England, a son and daughter, Queen Mary, of James II of England, and his brother, the Duke of Gloucester, the son of Louis XIV, and Louis, Duke of Burgundy. Others had the disease, but it did not prove fatal. Among these were Queen Anne of England, Peter III of Russia, Louis XIV of France, William III, and Queen Maria Theresa of Austria. We may judge of the prevalence of the disease from the words of Ben Jonson, who wrote: "Envious and foul disease, could there not be One beauty in our age and free from thee!" and again the words of George Bell of Edinburgh: "The smallpox ever since its introduction to Europe more than a thousand years ago has descended with undiminished violence from generation to generation." Dr. Lettson wrote in 1801: "In reflecting upon its ravages the mind revolts in horror." Smallpox before the days of vaccination was chiefly a disease of children, and the adult population consisted mainly of survivors of a childhood attack. In those days in Europe there were four hundred thousand deaths annually from smallpox. In the year 1702-1703 there were three thousand deaths among the French inhabitants of the city of Quebec. Each day the bodies were brought to a church or to the cathedral and at night buried together, sometimes by the score.

Cow pox vaccine was given to the world by Edward Jenner in the year 1798, and from that time the conquest of the scourge began and has now reached its culmination in practically ridding civilized countries of one of the most hideous plagues in the history of medicine.

Venereal Disease Control in Great Britain.—That the British Government is fully alive to the gravity of the problem of the venereal diseases and to the importance of doing everything possible for the improvement of the public health in this respect was made clear by the Rt. Hon. L. S. Amery, Secretary of State for the Colonies, in the opening address of the Imperial Social Hygiene Congress, recently convened under the presidency of Sir Auckland Geddes. The ancient policy of hushing up the evil, said the Secretary, could only give dangerous results, but happily that point of view has entirely vanished. In 1911 it was practically impossible to get a single member of Parliament to say a word about these diseases. When in that year Lloyd George, as a young member, pleaded for a recognition of these diseases, he felt almost an outcast. The changed outlook is indicated by the fact that in 1924 nearly 400,000 pounds was spent by the Government in improving the health of the country through venereal disease control measures. The situation, according to Mr. Amery, is distinctly hopeful, because, from the medical point of view, there is no range of disease so definitely capable of being dealt with and cured if public opinion is only strong enough. This weakness of public opinion, reflected in ignorance, indifference and fatalism, has been the great difficulty in the past. He concluded his address with the observation that by treating these diseases quite frankly as diseases, by making medical care easy and natural, and by removing all question of stigma, he believed that a solution of the problem could be arrived at.

DEXTROSE (Glucose), 50% SOLUTION

For Intravenous Use

Swan-Myers Company

A clear, practically colorless solution, containing 50% by weight of Dextrose U.S.P.X, prepared with double-distilled water and sterilized without the use of chemical preservatives.

The 50% Solution may be given directly into the veins if desirable, but it is usually diluted with sterile and freshly prepared distilled water or with physiological salt solution to make a 5% or 10% injection. The absence of preservative makes the solution especially desirable for oral and intrarectal use.

Packed in boxes of

6—20 cc. ampoules
25—20 cc. ampoules

The ampoules may be obtained through dealers or directly from the laboratory.

SWAN-MYERS COMPANY, Indianapolis, Ind.

Pharmaceutical and Biological Laboratories

CAPROKOL

(HEXYLRESORCINOL S & D.)

$C_6H_3(OH)_2C_6H_{13}$

Indicated in the treatment of infections of the urinary tract.
Approximately 45 times the germicidal power of Phenol.
Non-toxic in therapeutic doses.
Renders the urine a germicidal solution.

FOR ADULTS:—Soluble Elastic Capsules CAPROKOL, (Hexylresorcinol S & D.). Supplied in prescription boxes of 100. Each capsule contains 0.15 gram CAPROKOL, (Hexylresorcinol S & D.) in a 25% solution in Olive Oil.

FOR CHILDREN:—Solution CAPROKOL, (Hexylresorcinol S & D.). Supplied in four-ounce prescription bottles. Each teaspoonful contains 0.1 gram CAPROKOL, (Hexylresorcinol S & D.) in a 2 1-2% solution in Olive Oil.

SHARP & DOHME
BALTIMORE

New York Chicago New Orleans St. Louis Atlanta Philadelphia Kansas City San Francisco

Hospital Equipment of the Malolo.—Many who are still in the prime of life can remember the day when even on passenger liners of the better class the hospital facilities were crude and entirely inadequate. Conditions have improved greatly in recent years, however, and the progress that has been made is strikingly illustrated by the specifications for the hospital equipment of what is to be the largest and fastest high powered passenger steamer ever built in the United States.

The vessel is the *Malolo* (Hawaiian for *Flying Fish*) which is now being constructed for the Matson Navigation Company at Cramp's Shipyard, Philadelphia. When completed in the spring of 1927 she will be placed on the San Francisco-Honolulu run. With her 22,000 ton displacement, her 582 foot length, and her 83 foot beam she will be one of the finest vessels on the Pacific. Her speed of twenty-five miles an hour will enable her to make the round trip in four days less than the fastest vessel now plying between the two ports.

The passenger hospital will include two wards, a bath, dispensary, operating room, and an attendant's room. The crew hospital will consist of a ward and a bath. Each of the passenger wards will accommodate four persons, while the crew's ward will take care of six persons. In addition to the berths, each ward will be fitted with a desk, three white enamel hardwood chairs, and with portable trays of hardwood which can be attached to the berths for the use of patients when taking their meals.

The equipment of the operating room will include the usual operating table, anesthetist's outfit, sterlizing outfit, instrument and dressing cabinet, etc. The dispensary will be fitted out with the necessary desks, chairs, dressers, medicine cabinets, bottle racks, etc. The hospital will be floored throughout with special composition flooring and ceramic tile. The walls will be painted with white enamel.

The quality of the *Malolo's* accommodations as a whole will be in keeping with the complete and thoroughly modern equipment of the hospital. Her 600 passengers—all first class—will be accommodated in 274 staterooms. There will be 160 private baths. On "A" deck will be located the ballroom, lounge, library, smoking room, and veranda; all connected on the port side by spacious foyers and galleries. The main dining room, extending the full breadth of the ship, will be 108 feet long. At its forward end will be two alcove coffee rooms suitable for use as auxiliary dining rooms, or for private dinner parties.

A gymnasium, a swimming pool, and electric baths will be provided. A complete system of mechanical ventilation will be installed for use in the tropical climate which the vessel will encounter on her voyage to the Hawaiian Islands.

The total cost of this newest addition to the American merchant marine will be $6,500,000.

New Forms for Reporting Stillbirths.—New forms of stillbirth certificates came into use on January 1st. These certificates are printed on pink paper and combine all data necessary to record a stillbirth both as a birth and as a death.

It may be well to recall, says *Health News*, that a stillbirth is defined in the law as that of a child born dead after reaching the fifth month of uterogestation, that such a child must be registered as a birth and also as a death, that a medical certificate of the cause of death must be signed by the attending physician, if any, who should state "the cause of death as stillborn with the cause of the stillbirth, if known, whether a premature birth, and if born prematurely the period of uterogestation in months if known."

The purpose of this provision is to insure complete registration of this important class of births and infant deaths. Hitherto, a stillbirth had to be registered on too separate certificates—as a birth and as a death. To simplify the procedure, during the last session of the legislature the law was amended making possible the registration of a stillbirth on one certificate.

The procedure in filing these certificates will be similar to that of ordinary death certificates and the duty devolves upon the undertaker or person in charge of the burial. If the father or some member of the family desires to bury the body, the physician who attended the birth is requested to advise them to obtain a stillbirth blank from the local registrar, to fill it out carefully according to instructions printed on its reverse side, and obtain a burial permit prior to the burial or other disposition of the body within seventy-two hours after the occurrence of the stillbirth.

Hookworm Disease Spreads to Palestine.—Modern methods of agriculture are blamed for the introduction of hookworm into the Holy Land. Dr. A. Felix, of the Rothschild Hospital in Palestine, who found that about one out of every twelve workmen in the orange groves is affected by the disease, attributes it to the increased use of irrigation in the land. "It is very difficult to trace the source of the infection," said Dr. Felix, "but Egypt, where the hookworm disease is known to exist, is the most likely source because of the large number of Egyptian soldiers who worked here during the war."—*Science News-Letter.*

Venereal Disease Control in Great Britain.—That the British Government is fully alive to the gravity of the problem of the venereal diseases and to the importance of doing everything possible for the improvement of the public health in this respect was made clear by the Rt. Hon. L. S. Amery, Secretary of State for the Colonies, in the opening address of the Imperial Social Hygiene Congress, recently convened under the presidency of Sir Auckland Geddes. The ancient policy of hushing up the evil, said the Secretary, could only give dangerous results, but happily that point of view has entirely vanished. In 1911 it was practically impossible to get a single member of Parliament to say a word about these diseases. When in that year Lloyd-George, as a young member, pleaded for a recognition of these diseases, he felt almost an outcast. The changed outlook is indicated by the fact that in 1924 nearly 400,000 pounds was spent by the Government in improving the health of the country through venereal disease control measures. The situation, according to Mr. Amery, is distinctly hopeful, because, from the medical point of view there is no range of disease so definitely capable of being dealt with and cured if public opinion is only strong enough. This weakness of public opinion, reflected in ignorance, indifference and fatalism, has been the great difficulty in the past. He concluded his address with the observation that by treating these diseases quite frankly as diseases, by making medical care easy and natural, and by removing all question of stigma, he believed that a solution of the problem could be arrived at.

Healthy Recreation the Enemy of Venereal Disease.—The British Navy lost 325,557 days in the year from venereal diseases, according to a statement made by Surgeon Commander T. B. Shaw in a recent address before the Imperial Social Hygiene Congress. In commenting upon the relationship between venereal disease and prostitution, Commander Shaw stated that the abolition of brothels must in the end lead to a material reduction in venereal disease. He pointed out that in Gibraltar the marked decrease in the venereal disease incidence, particularly that of gonorrhea, coincided with the closing of the local brothels and the refusing to renew permits of residence to prostitutes. Healthy recreation, he insisted, was the enemy of the vice with which they were concerned, and that everything possible should be done to insure that seamen on leave would have facilities to indulge in healthy pursuits.

A Clinical Study of Van Den Bergh's Test in Jaundice.—C. H. Andrewes (*Quarterly Journal of Medicine*, October, 1924) presents the results of van den Bergh's test on 184 cases, divided in the following groups: cases of frankly obstructive jaundice; cases of frankly hemolytic jaundice; cases of jaundice not frankly obstructive nor frankly hemolytic; control cases, and in various pathological fluids (cerebrospinal fluid, plural effusions, etc.). As a result of this investigation he states that the test has a considerable clinical value as a method of quantitative estimation of bilirubin in the blood. It enables one to follow the progress of jaundice quantitatively and to detect it when latent. With its aid a pernicious anemia may be distinguished from a secondary anemia. Frankly hemolytic can be distinguished from frankly obstructive jaundice by means of the test, but as a means of differentiating icterus due to liver cell damage from other types of jaundice, the value of the method is slight. Theoretical reasons are advanced why liver cell damage should be able to cause either the direct or indirect diazo reaction. There is a kidney threshold for direct bilirubin corresponding to 3.5 or 4 units of bilirubin in the blood. Some slight individual variation occurs.

Good Faith With You!

The practicing physician has a right to expect that the remedies that seek his attention and patronage shall not be exploited to his patients. He—and he alone—is competent to treat the sick. Therefore, during the third of a century and more, that

Gray's Glycerine Tonic Comp.

(Formula Dr. John P. Gray)

has been serving the physicians of the country, it has never been advertised to the laity. In its manufacture, introduction and distribution, *"good faith with the medical profession"* has been the watchword.

Your card or letterhead will bring a regular 6-ounce bottle free of expense.

THE PURDUE FREDERICK CO.
135 Christopher St., New York

IT is easy to understand why Gray's Glycerine Tonic Comp. is today so widely used by discriminating practitioners. They know they can rely on its ethical standing no less than on its therapeutic efficiency.

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **Depressing Prostration** following **Influenza,** and in the **General Debility** of **Phthisis, Valentine's Meat-Juice** is recommended by many practitioners throughout the world as invaluable in their treatment.

Influenza *and* Phthisis.

Dr. Boulland, *Paris, France:* "In an attack of La Grippe accompanied by complete lassitude, I used VALENTINE'S MEAT-JUICE. With this preparation I established an excellent appetite and restored my strength very rapidly."

E. H. Walker, *Resident Medical Officer Boro Isolation Hospital and Boro Tuberculosis Sanatorium, Derby, England:* "I have pleasure in stating that I have found VALENTINE'S MEAT-JUICE valuable in the treatment of soldiers discharged from the Army suffering from Pulmonary Tuberculosis."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Public Health Nursing.—"Public health nursing, a specialized branch of general nursing, has been a natural development of the early work of ministration carried on by the bishops, priests, and deacons of the early church," writes Dr. J. G. Townsend, of the United States Public Health Service (*Public Health Reports,* November 6, 1925). We find a work of visiting nurse service being carried on in the third century as a part of church duty. The instructions for this were: "He is to administer to the infirm, to strangers and widows, to be a father to orphans, to go about into the houses of the poor to see if there is anyone in need, sickness, or any other adversity; he is to care for and give information to strangers; he is to wash the paralytic and infirm . . . He is also to visit inns and see if any poor or sick have entered or any dead are in them." For some reason the church later abandoned this work, so that from about 600 to 1600 A.D. there was no organized care of the sick in their homes.

Before the time of Vincent de Paul (1580-1660), visitations to the sick and their relief were on a basis of pure charity; rich and charitably inclined individuals contributed to the wants and needs of the so-called poor—there were no methods of determining what really constituted poverty. Vincent de Paul was the first to introduce the aspect of social service in home visits. He saw that charity was being carried too far and was encouraging pauperism. He insisted that the condition of the poor be investigated as to whether they could be helped to help themselves, and if this was possible, employment was found for them and they were put into a position of being in part, at least, self supporting. He opposed sending individuals to hospitals or asylums, without positive necessity, but believed in keeping family units intact, even though sometimes it was necessary to pay rent or supply house furnishings. "This was indeed a modern step for those times and is practically what social service in connection with public health nursing does at the present time."

Florence Nightingale's work in the Crimea fortunately brought to her attention the dire need for trained nurses, with the proper interpretation of the word "trained." As a result, in 1860 the first school for nurses was opened with an enrollment of fifteen. They were to have one year's training in the wards of the hospital, after which they were expected to remain one or two years as full fledged nurses. It was these fifteen nurses, disciples of Miss Nightingale, who, in their turn, acted as teachers and from whose efforts the nursing profession as we know it today had its real beginning. With the nursing personnel as it was in those times, it was possible to extend better scientific care, in the matter of district and home nursing, to the poor. William Rathbone of Liverpool has been credited with being the first to inaugurate district nursing. At an early age he was greatly interested in the problems of the poor, and in a practical way learned their needs by making personal visits through courts and alleys, calling from house to house, and so learning something of their medical needs. In order to try out his theories for bettering conditions, he employed a nurse who had been attending his wife and at his own expense obtained her cooperation in making these visits. The reports of her visits are most interesting. We learn that the nurse was instructed, not only to give nursing care to the sick, but to teach their families how to take care of themselves and of their own sick, and how to lead healthful lives. The results of this beginning were so satisfactory that other nurses were put on duty and the work grew rapidly. There was even then a tendency to get away as far as possible from actual medication and to emphasize public hygiene and prophylaxis, even though the knowledge of infectious diseases was at that time very meagre. We read that nurses were urged over and over again not to pauperize the patient by giving medical comforts unless they were absolutely necessary; Florence Nightingale wrote: "If district nurses begin by giving relief, they will end by doing nothing but giving relief."

Public health nursing in this country was rather slow in developing. In 1828 Dr. Warrington of Philadelphia, when he was only twenty-three years of age, inaugurated the society of district nursing. At first this gave only qualified nursing attendance to poor women in childbirth, but the work was gradually extended to include all classes.

A district nursing organization was started in Boston in 1886, and in 1888 the association was incorporated under the name of Instructive District Nursing Association, with the purpose not only of caring for the sick, but of giving them instruction in home nursing and public health.

The first special work in district nursing was undertaken in London in 1892, when a staff of visiting nurses was organized to visit schools and inspect school children. Miss Lillian Wald, founder of the Henry Street Settlement, suggested in 1902 the use of the nurse to supplement that of the doctor in the schools of New York. Medical inspection of school children had been in vogue before that time, but was merely a perfunctory examination by a physician, the only thing accomplished being the exclusion of the child—nothing to prevent illness or to instruct the home family in healthful living and proper care was done.

Throughout this time when the public health nurse was making her services more and more frequent and valuable, gradual progress was being made in the requirements of those entering the nursing profession; also, great strides were being made in the medical profession toward the prevention of disease; the dangers of neglected teeth, tonsils and adenoids were becoming known, and the value of scientific infant care. Last came the awakening to the fact that a real health problem exists in the country—one of even greater importance than the urban health question. Country death rates were found to be higher, the morbidity index higher, and lack of protected water and milk supplies, of proper sewage disposal as dangers to which the city dweller is not so subject.

Dr. Townsend concludes his article with the statement that public health nursing is still in its infancy, and that the future holds unlimited service for this branch of the profession. "The difficulty is to find workers; and it is our duty as public health workers to present this problem before the nursing profession with a plea for the *trained* worker."

DIABETES, TOXEMIA AND DIABESAN

Dr. C. A. M. of Atlantic City, New Jersey, writes us under date of January 20th, 1926, as follows:

"Gentlemen:

Kindly send me one thousand (1000) tablets of Diabesan. I am using your Diabesan in many cases of intestinal toxemia and diabetes with surprising good results.

Enclosed please find check.

With my best regards,

Yours,

(Signed) C. A. M., M.D."

Diabesan is efficacious and harmless. There is no danger of an overdose.

The Prevalence of Defective Vision.—Defective eyesight is affecting the country's industrial output, is handicapping education, and is a growing menace to human welfare, says the Eye Sight Conservation Council of America in a comprehensive eyesight survey of two years' duration covering the entire field of eyesight conservation. The deleterious influence of eye defects and eye diseases, it is declared, is a challenge to civilized effort in social control. Massing all existing data, and supplementing it with the results of original research, the Council finds that defective vision is widespread among industrial workers and school children, and that it is a prolific source of waste in industry and education.

Summarizing conditions in education, the report called the most comprehensive of its kind ever completed in this country, says that twenty-five per cent. of the school children in the public schools of the United States "have manifest defects of vision and symptoms of eyestrain." This result was reached through simple visual acuity tests. The survey, it is stated, covers eye tests of more than 14,200,000 school children and students enrolled in public schools, state normal schools, universities and colleges.

Defective vision is increasing among older students, the survey in colleges and normal schools indicates. In sixteen state normal schools and twenty-three colleges and universities having a total enrollment of approximately 100,000 students, 54,695 tests were made, showing that 18,706 or forty per cent. had defective vision.

Two thirds of those reporting found defective vision within the range of from thirty-five to fifty per cent. "It is safe to assume," says the report, "that this prevalence of defective vision among these students at the beginning of their university studies was undoubtedly higher than in their earlier years."

Poor eyes, it is disclosed, induce retardation and are responsible in some measure for the backward student. "The proportion of retardation found among four groups of school children with defective vision, totalling 28,667," the report continues, "varies from sixty to eighty-five per cent. and averages sixty-seven per cent. The prevalence of defective vision, found among six groups of pupils retarded in their progress, varies from twelve to eighty-one per cent."

Eyesight, as an important factor affecting the output of the industries of the United States, is being overlooked, the report asserts. A survey was made to determine the prevalence of visual defects among industrial workers and the methods practised by industrial concerns for examining the eyes of their employees. Information was furnished by 170 companies situated in twenty-three states and employing over one million persons. The data furnished by forty companies were complete enough for adequate summary and comparison.

"The records of these forty companies," the report adds, "cover the examinations of the eyes of 204,817 employees. Even though the prevalence of defective vision was reported by one company as low as 5.3 per cent., which is no indication of the true condition, the average proportion of defective vision as reported by the forty companies was 44.3 per cent.

"The records from twenty companies of 150,782 eye examinations or 77 per cent. of the 204,817 examinations reported showed the prevalence of defective vision ranging from 48.3 per cent. to 79.2 per cent. and averaging 54 per cent.

"This group of 200,000 industrial eye examinations is many times larger than any group that has previously been studied for the purpose of arriving at definite conclusions. It is considered sufficiently large and properly distributed both geographically and according to the type of industry to establish an accurate incidence of the proportion of defective vision among the 42,000,000 gainfully employed persons in the United States."

Sections of the report, compiled by Joshua Eyre Hannum, research engineer of the Eye Sight Conservation Council of America, and edited by Guy A. Henry, the Council's general director, deal with eye hygiene, eye diseases, eye defects, eyesight and education, eyesight and occupation, eye protection, and illumination of school and home.

One section tells of the struggles with poor eyesight of noted persons, including Francis Parkman, Tschaikowsky, George Eliot, William Wordsworth, Theodore Roosevelt, Goethe, Margaret Fuller, Jonathan Swift, John Greenleaf Whittier, H. G. Wells, Honore de Balzac, Adelaide Ristori, Basil King, Taine, and Nietzsche. Whittier, it is said, was color blind, and Taine was crosseyed. Relentless use of the eyes, according to the report, hastened the death of Balzac.

Voltaire, Mr. Shaw, and the Doctors.—Dr. Rolleston has been reminding the Royal Society of Medicine, says the *Manchester Guardian Weekly*, that Voltaire was a great apostle of inoculation against smallpox. More than that, he was a powerful advocate of the profession and a relentless foe of the quack. Perhaps Dr. Rolleston had an eye, as he spoke, on a modern man of letters, who is sometimes compared to Voltaire. Yet perhaps if Mr. Shaw had lived in those days, he would have been on the same side as the great Frenchman. For Voltaire saw two forces in conflict—the obscurantism that was almost all that was left at the moment of the official religion of France, and the eager spirit of inquiry represented by the men of science and the Encyclopedists. In that struggle he was ready to play a modest as well as an heroic part. For when asked to write on Hemistichs for the Encyclopedia he replied: "'Tis not a very brilliant task, but perhaps the article will be useful to men of letters and amateurs. One should disdain nothing, and I will do the work if you choose." Medicine was at a low ebb in France, and it was not until the struggle had ended in a catastrophe which Voltaire could not foresee that it began to advance. In England, on the other hand, medicine was taking its first steps in the eighteenth century as a social and public science, and England was the home of philosophies and movements that Voltaire admired. Voltaire, looking round him, saw the Jansenist persecutions and welcomed any organization of scientific effort. Mr. Shaw, looking round, sees Harley Street where Voltaire saw the Parliament of Paris, and the quack where Voltaire saw the professional doctor. And, however much Mr. Shaw may differ from Voltaire, he resembles him in this: that if he thinks he has a case to put, he takes care that it shall not be misunderstood.

DEXTROSE (Glucose), 50% SOLUTION

For Intravenous Use

Swan-Myers Company

A clear, practically colorless solution, containing 50% by weight of Dextrose U.S.P.X, prepared with double-distilled water and sterilized without the use of chemical preservatives.

The 50% Solution may be given directly into the veins if desirable, but it is usually diluted with sterile and freshly prepared distilled water or with physiological salt solution to make a 5% or 10% injection. The absence of preservative makes the solution especially desirable for oral and intrarectal use.

Packed in boxes of

6—20 cc. ampoules
25—20 cc. ampoules

The ampoules may be obtained through dealers or directly from the laboratory.

Deaths of Physicians in 1925.—During 1925 the deaths of 2,483 physicians in the United States were recorded in the *Journal A. M. A.*, almost the same number recorded in the previous year, which was 2,486. To make a comparison of the two years, the present tabulation will follow closely the editorial of last year. Adding two per cent. to the total number of deaths reported, on account of delayed reports and possible omissions, we estimate the number of physicians who died during 1925 at 2,532. With a total of 147,010 physicians in the United States, the number of deaths is equivalent to an annual death rate of 17.22 per thousand, which is a slight decrease over last year. The average annual death rate for physicians, as computed by the *Journal A.M.A.* for the last twenty-four years, is 17.08.

AGES

The age at death of 2,448 physicians whose age was stated varied from twenty-five to one hundred and seven years. Twenty-one of the decedents were under thirty years of age; 119 were between thirty-one and forty; 368 between forty-one and fifty; 560 between fifty-one and sixty; 665 between sixty-one and seventy; 489 between seventy-one and eighty; 207 between eighty-one and ninety, and eighteen between ninety and ninety-nine. There was one death at the age of one hundred and seven. The largest number of deaths occurred at ages sixty-six and sixty-seven, the number dying at each of those ages being seventy-nine. The largest number of deaths reported at any given age last year was at sixty-five. There were more deaths reported in August than in any other month (243); the smallest number was reported in December (155).

CAUSES OF DEATH

Among 2,420 reported deaths for which specific causes were given, diseases of the circulatory system accounted for 872, the largest number by systems. Of these, heart disease caused 559 deaths, angina pectoris being specified in ninety, myocarditis in eighty-one, acute dilatation in twenty, endocarditis in fourteen and valvular disease in twelve; cerebral hemorrhage was specified as the cause of 233 deaths, and was the second most frequent cause given, as it was last year. Diseases of the respiratory system, exclusive of tuberculosis, accounted for 278 deaths, of which 222 were due to pneumonia, twenty-six to influenza, twelve to asthma, four to pulmonary edema, and two to cancer of the lung. Diseases of the genitourinary system caused the death of 227 physicians, of which number 161 were due to nephritis, forty-one to uremia, fourteen to diseases of the prostate, and one to hypernephroma. Diseases of the digestive system, exclusive of cancer and diabetes mellitus, accounted for 108 of the deaths reported, of which thirty-three were due to appendicitis, sixteen each to peritonitis and cirrhosis of the liver, nine to gastric ulcer, two to duodenal ulcer, thirteen to cholecystitis or gallstones, ten to acute intestinal obstruction, two to abscess of the liver, two to enteritis, and one each to atrophy of the liver, pancreatitis and colitis. Among the socalled general diseases, cancer accounted for 118 deaths. The organs most frequently cancerous were the stomach, twenty-six; intestine, twelve; pancreas, eight; prostate, seven; throat and adjacent parts, eleven, and the liver and bladder, each six. Tuberculosis under this classification was the second most frequent cause of death given, with fifty-two; then erysipelas, eight; typhoid fever, seven; scarlet fever, two; leucemia, three; diphtheria, alcoholism, pellagra, acute articular rheumatism and purpura hemorrhagica, each one. Diseases of the nervous system caused seventy-three of the deaths reported, of which nineteen were due to some form of paralysis; nine each to brain tumor and meningitis; seven to paresis; six to epidemic encephalitis; five to insanity; two each to multiple sclerosis, hiccup, brain abscess and paralysis agitans, and one each to concussion of the brain, tumor of the spinal cord, and transverse myelitis. The cause was not given in sixty-three deaths reported, and 234 deaths were ascribed to senility, each of the decedents being more than seventy years of age, with no other cause stated. It is obvious that there is much to be learned about causes of deaths among aged physicians, and assistance in ascribing more definite causes will be greatly appreciated from all persons who send reports.

ACCIDENTS AND HOMICIDES

There were eighty-three deaths reported due to accidents. The automobile was responsible for forty; falls, fourteen; drowning, seven; firearms, six; burns, four; grade crossings, three; asphyxiation, three; röntgen ray burns, two; poison, two; the airplane, street car and electric shock, each one. There were three homicides; last year, thirteen.

SUICIDE

Fifty-nine physicians ended their lives by suicide: thirty with firearms, five with poison, four with morphine, two with phenol, two by drowning, two by jumping from windows, and one with gas; in thirteen instances the method was not stated.

POSITIONS

Among the physicians who died during the year 1925, there were 137 who served in the World War; eighty-two who were Civil War veterans, and twenty-three who were Spanish-American War veterans. There were eighteen who had been members of state legislatures; eighty-three, members of boards of health; fifty-four, members of boards of education; nine, members of boards of medical examiners; eighteen, mayors of cities; twenty-six, coroners; five, postmasters; fifteen, authors; two, editors; ten, bank presidents; four, lawyers; four, dentists; twenty-one, druggists, and one, a missionary.

RÉSUMÉ

Looking back twenty years, we find that sixty-two physicians died under thirty years of age in 1905, while in 1925 there were only twenty-one; then, there were 103 who died between seventy and eighty years of age, whereas in 1925 there were 489; then, there were 239 who died between eighty and ninety years of age, and in 1925 there were 207 between eighty-one and ninety; then, there were twenty-five who died beyond ninety years of age, and in 1925 there were nineteen; then, there were two who passed the century mark, and last year there was only one.—*Journal A. M. A.*, January 9, 1926.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

Syphilis and Heart Disease.—The relation between syphilis and cardiac disease was discussed at the recent sessions of the Imperial Social Hygiene Congress (British) by Colonel Sir Leonard Rogers, representing the Government of India. He said that practically the whole of heart disease in India was due to syphilis and concluded that the eradication of it would reduce heart trouble there to negligible proportions.

In this connection it might be observed that India is not alone in recognizing the great socioeconomic problem of controlling syphilis. The United States Public Health Service has recently issued a compilation of abstracts relating to visceral syphilis for use in its cooperative work with the State departments of health in the control of venereal diseases. These abstracts reflect the causative influence of syphilis in diseases of the heart, aorta and peripheral bloodvessels. Special attention is being given in all countries to the prevention of these diseases by prompt adequate treatment in the early stages of syphilis before the heart and bloodvessels become involved.

Charts Showing Posture Standards.—The Children's Bureau of the United States Depatrment of Labor will issue early in 1926 a set of six charts on posture standards for boys and girls, intended for the use of physicians, nurses, physical education teachers, and clinics.

The charts were planned on the basis of extensive observation and measurement of school children by Dr. Armin Klein, of Boston, who is in charge of posture clinics for the Massachusetts General Hospital and the Department of Health of the city of Boston. They will be useful, it is believed, in affording visual illustrations of posture types and groups for purposes of classification and comparison. In devising the charts it has been recognized that there are certain distinct types of physique and that the standards of good and bad posture must be considered in relation to the physical type. Three types of figures are shown for both boys and girls—the thin, the intermediate, and the stocky. Each chart shows four silhouette figures illustrating excellent, good, poor, and bad posture for one type of girl or boy.

Descriptions of the distinguishing characteristics of excellent, good, poor, and bad posture are printed on each chart. In excellent posture, the charts point out, the head is up and the chin in; in good posture the head is slightly forward, in poor posture it is forward, in bad posture it is markedly forward. In excellent posture the chest is up and the breast bone is the part of the body farthest forward, in good posture the chest is slightly lowered, in poor posture it is flat, in bad posture it is depressed or sunken. In excellent posture the lower abdomen remains in and flat, in good posture it is in but not flat, in poor posture it is relaxed and is the part of the body farthest forward, in bad posture it is completely relaxed and protuberant. In excellent posture the curves of the back are within normal limits, in good posture they are slightly increased, in poor posture they are exaggerated, in bad posture they are extremely exaggerated.

Each chart is approximately twenty-four by thirty-four inches. A limited number of the charts are available for free distribution; others may be secured from the Government Printing Office.

Valentine's Meat-Juice

Whenever the **Stomach** from any cause **Rejects Food** or **Medicine, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.** In the **General Debility** with **Impaired Digestion** of **Phthisis,** and in the **Depressing Prostration** following **Influenza** it is recommended by many practitioners throughout the world as invaluable in their treatment.

Phthisis.

J. Mertens, M. D., *A. T. O. Bristol Municipal Tuberculosis Dispensaries, Bristol, England:* "I am pleased to state that the results obtained from VALENTINE'S MEAT-JUICE were very satisfactory indeed in all cases where no other kind of food could be used. It produced excellent results with wounded soldiers suffering from Tuberculosis of the lungs."

Dr. Gouel, *Physician in Chief Villepinte Hospital for Consumption, Paris, France:* "VALENTINE'S MEAT-JUICE succeeds well in cases of Anæmia and in the treatment of Tuberculosis in an advanced stage when the stomach is intolerant."

Physicians are invited to send for brochures containing clinical reports.

For sale by American and European Chemists and Druggists.

VALENTINE'S
PREPARATION
NUTRIO PERMIE
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS-Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Miscellany.

Knights of St. John.—It is reported that the English Grand Priory of St. John has just acquired the freehold of a small portion of the historic site, now known as the Muristan, upon which stood the great Hospital of St. John in Jerusalem, says the *Medical Press and Circular,* January 13, 1926. Nearly seven and a half centuries have passed since the Crusaders' Kingdom of Jerusalem fell before the victorious Saladin, and the Hospitallers were expelled from the Holy City. Their great hospital contained separate wards for men and women, a hospice for pilgrims, the Convent of St. Mary Magdalen which provided the nursing Sisters for the sick women, and the administrative offices of the Order with accommodation for some two hundred knights, who attended upon the male patients, and the storerooms and dispensaries of the hospital. It is said that Saladin used one part of it as a palace and made a lunatic asylum of another, and that in later years a Moslem hospital carried on the ancient traditions associated with the site. Before the conquest of the Crescent, a visitor recorded that as many as two thousand sick persons were at one time within the wards of the hospital, and the Grand Master, in 1177, ten years before Saladin's entry, wrote in a letter that seven hundred and fifty men, wounded in action, and nine hundred civilians, had been admitted for treatment. The Church of St. John, which dates from Byzantine times, still survives, and at the invitation of the Patriarch of Jerusalem the Knights of the English Grand Priory, in the pursuit of their mission, will make use of one of its chapels. Ere long the traveler will see another Hospital within the Muristan.

La Politique du Médecin of J. O. de la Mettrie.—*Medicina* for November, 1924, reprints some extracts from a curious libel published in 1746, condemned to be burned by the Parliament of Paris, and whose author, Julien Offray de la Mettrie, had to flee to Leyden. *La Politique du Médecin de Machiavel* had a scandalous success; altogether forgotten today, it is nevertheless for the history of physicians of the eighteenth century of incontestable documentary value. Under his transparent pseudonyms, de la Mettrie sketched with a pencil pitiless and cruel, often scurrilous, sometimes unjust, the portraits of contemporary doctors.

Let us quote the following lines from the chapter devoted to Astruc (Chrysologue): "Here is still another wise man, but a lesser light. Geometrician —a bad geometrician—entomologist, antiquary, theologian—Molinist theologian, to please the Jesuits whose physician and cardinal he is—and he has prudently made of this a support; lawyer, politician, historian, naturalist, doctor . . . He has studied everything, learned everything, except his profession . . . But this man who is all and nothing, has imposed upon it all a universality of knowledge necessarily superficial." Jean Astruc was consulting physician to Louis XV.

The best portrait of all is that of Sylva, also consulting physician to the king. See with what art de la Mettrie deals with this personage: "Who is this physician who ascends into his equipage with so much éclat that the commotion is heard from one end of the court to the other; whom they sustain as he dismounts; and whom they bear in some way even up to the Grand Stairway itself. It is la Forest! What handsome horses! With what art does the coachman make them paw the air and turn about at the command of the master; the noise they make announces this brilliant personage, but does not prevent him from halting to talk of serious matters with one of his colleagues. . . . But there is a chamber maid passing; he stops suddenly to approach her, and asks her about her health. What pretty things he says! With what a gay manner he follows her out of sight. He returns anon and resumes the thread of the conversation. . . . 'Let us always,' he says, 'be kind to chamber maids; they make it up to us in their mistresses' toilettes.'" He goes on to paint the author, the man, and the gallant doctor. . . . As to the man, there is a most indiscreet reminiscence of unfortunate conjugal experiences, and he passes on to the gallant doctor, of whom he dissertates at length, for he was, he says, "both indecent and immoral." He cites many other anecdotes little edifying, paints complacently his affairs with his beautiful clients, whom he chose, he says, with all the indiscretion of a libertine, without respect for rank, nor for dignity, boasting of favors that he had never even asked for."—*Translated from Æsculape.*

Curious Privileges of Provençal Students in the Fourteenth Century.—Prof. Chauvin of Marseilles, devoting the first lesson in his course in urology to ancient faculties of medicine of the Provençal region, said that we must return to the ninth century for the beginning of medical science in Provence, as in the rest of the middle of Europe. It was in 1303 through a bull dated at Anagni that Pope Boniface VIII created the University of Avignon, where were taught civil and religious law, medicine and the liberal arts. Created by the pope, protected by the king Charles II, richly endowed, the university did not wait long to shine brilliantly as an educational center. Created a little later by Louis II, king of Sicily and Naples, the faculty of Aix followed a like development. Both during the centuries were rivals in learning and zeal; both grew dark at the same time in the cataclysm of the Revolution.

From the very interesting talk which Prof. Chauvin devoted to the history of these two ancestors of the young school at Marseilles, let us quote a few lines relating to the privileges accorded to the students of Provence: "They were exempt from taxes and protected against the police. . . . For them were created, by the princes of the Church or by the laity colleges where youths without means were received. From the fourth century there existed at Montpelier four colleges; there were at least eight at Avignon, of which two received gratuitously thirty-six students each. Aix possessed none and when the king René established six funds for poor students, he sent them to the college of Roure in Avignon. Fed and lodged, the student, then, had only to provide his pocket money, which they did by employing some methods which in our day would be considered lawless and barbarous in the extreme."—*Translated and abstracted from Æsculape.*

The Commonwealth Fund.—In the seventh annual report, issued recently, announcement is made that gifts totaling $1,339,000 for scientific, educational and humanitarian work were made by the fund during the year ending September 30, 1925.

Child welfare has been one of the chief interests of the fund since its organization, and two major projects in this field, involving grants to a dozen different organizations, received approximately $847,000 of the fund's income during the past year. Appropriations totaling $425,000 were shared by the National Committee for Mental Hygiene, the National Committee on Visiting Teachers, the Joint Committee on Methods of Preventing Delinquency, and the New York School of Social Work, in a continuing program of child guidance and the prevention of delinquency. This program, initiated by the Commonwealth Fund in 1921, has already resulted in the establishment of psychiatric clinics for the study of "problem children" in seven American cities, while visiting teacher service has been organized in ten representative communities throughout the country.

Additional grants made by the Commonwealth Fund in the field of mental hygiene included $10,500 to the Children's Memorial Clinic in Richmond, $36,000 to the University of Pennsylvania School of Medicine for psychiatric fellowships, $15,000 to the College of Physicians and Surgeons, Columbia University, for the development of its psychiatric clinic, $5,500 to the Berkshire Industrial Farm for the study of case records of delinquent boys, and $6,000 to the Smith College School of Social Work for fellowships in psychiatric social work.

Appropriations totaling $241,000 were made for the fund's child health program, which includes community demonstrations in Fargo, N. D., Athens, Ga., Rutherford County, Tenn., and Marion County, Ore. Another branch of the child health program is being pursued in Austria, where one hundred and four child health stations are being operated, together with a variety of supplementary work involving last year a grant of $100,000.

The most recent enterprise of the fund is a program of assistance to rural communities in establishing hospitals. A gift of $85,000 for a small hospital at Murfreesboro, Tenn., while not strictly a part of this program, marks the first definite effort of the fund along this line, and studies are being continued for the development of a plan which will provide for the construction of two rural hospitals each year.

Among miscellaneous special grants during the past year were the following: $15,000 to the American Society for the Control of Cancer for its educational campaign; $40,000 to the Foreign Language Information Service for Americanization work; $22,850 to the Hunan-Yale College of Medicine in China; $20,000 to the National Association of Travelers' Aid Societies; $15,000 to the National Board of Medical Examiners for the furtherance of standardization and reciprocity in the licensing of medical practitioners throughout the United States; $7,500 to the Presbyterian Hospital for research work; $6,000 to New York University for research in scarlet fever immunization.

Miscellany.

Size of Families.—The Department of Commerce announces that in 28 states there were 270,045 women aged 35 to 44 years of age who became mothers in 1924 and who had husbands engaged in gainful occupations.

The total number of children ever born to these mothers, including the births of 1924, was 1,708,927, or an average of 6.7 per mother, and the total number living was 1,450,608, or an average of 5.3 per mother.

Of these mothers 202,460 were aged 35 to 39 years, and for mothers of this age group the average number of children ever born was 5.9 and the average number living was 5, while for 67,585 mothers aged 40 to 44 the average number of children ever born was 7.3, and the average number living was 6.2.

Considering only mothers aged 35 to 39 years, the highest average number of children ever born (7.4) appears for the wives of coal mine operatives and the lowest average (3.3 each) for the wives of chemists, assayers, and metallurgists, dentists, physicians and surgeons, and technical engineers; the highest average number of children living (6) appears for the wives of coal mine operatives and the lowest average number of children living (2.9 each) for the wives of dentists and technical engineers.

Considering only mothers aged 40 to 44 and only those occupations represented by at least 100 births, the highest average number of children ever born (9.1) appears for the wives of other mine operatives and the lowest average (4) for the wives of lawyers, judges and justices; the highest average number of children living (7.5) appears for the wives of other mine operatives and the lowest average number of children living (3.6) for the wives of lawyers, judges, and justices.

Distribution of Rat Virus Contrary to Law.—The necessity for the extermination of rats is acknowledged by everyone. The only question that arises is the choice of method; the one most effective in destroying the rat and the least dangerous to man is, of course, the one most desired.

Cultures of bacteria infectious to the rat, the so-called "rat viruses," have been extensively advocated for the purpose. It has been claimed that they destroy a high percentage of the rats exposed, and that they are harmless to man. Scientific investigations, however, do not bear out these claims. Following studies into the efficacy of the various rat viruses, Rosenau in 1901 and Bainbridge in 1909, reported a limited range of efficiency; the viruses killed only from 20 to 50 per cent. of the rats exposed and the survivors frequently developed an immunity to the culture or became carriers of the organism. Chemical poisons, on the other hand, killed 60 per cent. or more of the animals exposed. Moreover, the innocuousness of rat viruses for man has not been proved. Handson and Williams in 1908 reported an epidemic of enteritis following the use of one of these cultures. Recently, in the *Journal of the American Medical Association,* Spray reported an outbreak of 135 cases of acute gastrointestinal disease in the West Virginia University due to food contaminated as a result of the use of a commercial rat virus.

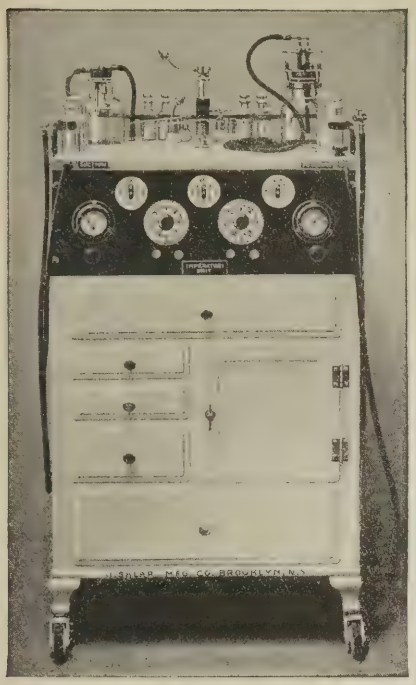
The distribution, by sale or otherwise, of living cultures of disease inducing bacteria, which include rat viruses, is prohibited in New York State unless approval has been obtained from the State Commissioner of Health.—*Health News,* February 15, 1926.

Cattle Tuberculosis.—Carrying the campaign of eradicating animal tuberculosis to areas where it is very strongly entrenched is one of the newer developments in the nationwide program to rout the disease. A survey just completed by the Bureau of Animal Industry, United States Department of Agriculture, shows the aggressive action taken by many counties.

The eradication of tuberculosis under the "area" plan is now being conducted in 34 of the 98 counties having more than 15 per cent. of tuberculosis infection among cattle, and in 54 of 165 counties containing cattle that are tuberculous to the extent of more than 7 per cent. but not more than 15 per cent. Thus, about one-third of the most badly infected counties have eradication work under way. Two of the counties, formerly very seriously affected, have already reduced the infection to 0.5 per cent. or less and are in the "modified accredited area" class.

There are 241 counties in the country where tuberculosis among cattle exists to the extent of more than 3 per cent. and up to 7 per cent. Of these counties 93 are conducting area work to eradicate the disease and 8 of them already have qualified as modified accredited areas. The work is also going forward rapidly in the more lightly affected areas where sentiment strongly favors eradicating the disease before it becomes more serious. At the beginning of 1926 the list of modified accredited areas totalled 149 counties, thus indicating excellent progress toward the conquest of the disease.

Marriage in Norway.—Since 1919 restrictive marriage laws have been in force in Norway. The inhibitions against marriage apply to any person who is insane or suffering from syphilis in an infectious stage. Gonorrhea (still infectious), epilepsy or leprosy forbids marriage, unless the other party to the contract is cognizant of the fact, and both have been warned by a doctor of the dangers of the disease. Doctors are compelled to notify the authorities if they, professionally or otherwise, become cognizant of the existence of these forms of disease in one who is contemplating marriage. If one of the parties has been insane, and has not been certified as cured, or if either is thought to be at present insane, a certificate must be provided indicating that insanity is not at present demonstrable. A person who was insane at the time of marriage may claim dissolution and a divorce may be obtained by the other party if he or she was ignorant of the insanity at the time of marriage. Certain questions have to be answered by both parties in writing, among others being particulars of relationship by birth or marriage, of previous marriage, and of previous children born out of wedlock. In the case of false statements two years' imprisonment may be inflicted.—*Medical Press and Circular,* December 2, 1925.



New and Different!

That best describes the

IMPERATORI

Treatment and Diagnostic Unit

Different in Quality, Design and Construction from any unit heretofore presented to the profession. A *complete* treatment cabinet into which is built all the usual and necessary aids to diagnosis and treatment that are considered standard in the treating of the nose, throat and ear.

DIABETES, TOXEMIA AND DIABESAN

Dr. C. A. M. of Atlantic City, New Jersey, writes us under date of January 20th, 1926, as follows:

"Gentlemen:

Kindly send me one thousand (1000) tablets of Diabesan. I am using your Diabesan in many cases of intestinal toxemia and diabetes with surprising good results.

Enclosed please find check.

With my best regards,

Yours,

(Signed) C. A. M., M.D."

Diabesan is efficacious and harmless. There is no danger of an overdose.

An Analysis of Twenty Fatal Diphtheria Cases.—The Division of Communicable Diseases of the New York State Department of Health has analyzed supplementary reports, received during October, on twenty deaths from diphtheria.

Only five of the patients were visited by a physician on the first day of the disease. Four were first visited on the second day, three on the third, one on the third or fourth, four on the fourth, two on the fifth and one on the seventh. Thus in three fourths of the cases parents were apparently negligent in failing to call a physician on the first day of illness.

The analysis was made in an effort to place the responsibility for these deaths, with the following results:

Parents apparently wholly responsible	9 cases
Physicians apparently wholly responsible	5 cases
Parents and physicians responsible	6 cases

According to the reports, the following omissions and mistakes were made presumably by physicians in the treatment of these patients:

Delay in administration of antitoxin (Of tese, result of culture was apparently awaited in 2 cases)	7 cases
Failure to administer antitoxin	2 cases
Subcutaneous method of administration used	4 cases
Insufficient dosage of antitoxin	5 cases
Antitoxin administered on more than one day	8 cases
Failure to adopt surgical measures in laryngeal type (where death occurred from respiratory obstruction)	2 cases

In two cases no antitoxin was administered, as the physician maintained in one case that it was "septic tonsillitis" and in the other that it was "streptococcus tracheobronchitis." As apparently no culture was taken in either of these cases, it would seem that the burden of proof is on the physician.

No culture was taken in four cases, and in three other cases there was apparently no culture taken. This is in violation of the sanitary code, which requires that cultures be submitted from all persons affected with or suspected to be affected with diphtheria. It should be remembered, however, that cultures in suspected diphtheria cases should not be relied upon for diagnosis. If the disease can reasonably be suspected, antitoxin should be administered at once in sufficient dosage.

Recent reports seem to indicate that insufficient dosage of antitoxin is becoming relatively rare. Much improvement, however, is needed in the direction of giving the patient the benefit of the doubt where diphtheria may be suspected, first in eliminating delay before giving antitoxin, and second in adopting the intramuscular method, or, in severe or late cases, the intravenous method of administration.

New York City Saves 417,000 Lives in Thirty Years.—According to a report just issued by Dr. William H. Guilfoy, Registrar of Records, New York City, if the infantile death rate of 1892 had continued throughout the succeeding years 843,007 children under five years would have died in the old city of New York (Boroughs of Manhattan and Bronx) between January 1, 1893, and December 31, 1922. But in these years the total number of deaths was 425,281, which means that 417,726 lives have been saved in these thirty years.

A New Instrument for a Common Disease

Ninety percent of adults over 40 have diseased gums. Toothbrushes in use are septic and if the gums are tender, the bristles prick or scratch these delicate tissues and "vaccinate" them.

Diseased gums have been difficult to cure because after a dental treatment the patient returns home and re-infects himself with the contaminated brush.

RE VIRA

provides a simple and sanitary method of cleaning the teeth and massaging the gums in all mouth infections, including Pyorrhea, Vincent's Angina, etc.

A new pad is used with each cleaning of the teeth and massaging of the gums. Pads may be used dry first between the teeth, then wet like an ordinary brush.

Outfits—holder and box of refill pads—Adults $1. Child's $0.75. Extra pads always available.

DEXTROSE (Glucose), 50% SOLUTION

For Intravenous Use

Swan-Myers Company

A clear, practically colorless solution, containing 50% by weight of Dextrose U.S.P.X, prepared with double-distilled water and sterilized without the use of chemical preservatives.

The 50% Solution may be given directly into the veins if desirable, but it is usually diluted with sterile and freshly prepared distilled water or with physiological salt solution to make a 5% or 10% injection. The absence of preservative makes the solution especially desirable for oral and intrarectal use.

Packed in boxes of

6—20 cc. ampoules
25—20 cc. ampoules

The ampoules may be obtained through dealers or directly from the laboratory.

SWAN-MYERS COMPANY, Indianapolis, Ind.

Pharmaceutical and Biological Laboratories

CAPROKOL

(HEXYLRESORCINOL S & D.)

$C_6H_3(OH)_2C_6H_{13}$

Indicated in treatment of infections of the urinary tract.
Approximately 45 times the germicidal power of Phenol.
Non-toxic in therapeutic doses.
Renders the urine germicidal.

FOR ADULTS:—Soluble Elastic Capsules CAPROKOL (Hexylresorcinol, S & D.)
FOR CHILDREN:—Solution CAPROKOL (Hexylresorcinol, S & D.)

Automobile Fatalities Reach a New Maximum.—The Metropolitan Life Insurance Company's *Statistical Bulletin* for January states that, as has been the case every year since 1911, the death toll of automobile accidents again increased among Metropolitan policyholders. The actual number of deaths recorded was 2,724 as compared with 2,456 in 1924, and the death rate rose from 15.9 per 100,000 to 16.7. The death rate from this type of accident has increased 50 per cent. since 1920; has more than tripled since 1915; and is now seven times as high as it was in 1911.

Some idea of the growing importance of automobile fatalities may be gained by comparing their death rate in the years 1915 and 1925 with those for certain other causes of death. In 1915, for example, there were two and one half deaths from typhoid fever to every one automobile fatality; in 1925 there were almost four deaths in automobile accidents to every one from typhoid fever. In 1915 there were more deaths from measles than from automobile accidents; in 1925 the death rate for the latter exceeded the measles rate approximately sevenfold. Ten years ago the combined death rate for the four principal communicable diseases of childhood was about seven times as high as that for automobile accidents, and diphtheria alone caused four times as many deaths as did the motor vehicle; but in 1925 the number of deaths from all four diseases combined does not greatly exceed the death toll of the automobile; and the latter now kills three persons to diphtheria's two. The automobile death rate in 1915 was higher than that for diabetes, whereas ten years ago the latter killed three times as many as did the auto. More than one quarter of all the accidental deaths in 1925 were caused by the automobile, which was responsible for only one in every thirteen of the fatal accidents in 1915. Ten years ago, three deaths occurred in railroad accidents to every two due to automobiles; but in 1925 there were nearly four and one half times as many caused by the automobile as occurred in railroad casualties.

Furthermore, automobile casualties have now become one of the worst scourges of childhood. Approximately forty per cent. of these deaths are among children under fifteen years of age. The automobile today is as great a menace to child life as scarlet fever and whooping cough combined.

Embryological Material.—The importance of embryology and of the study of intrauterine changes, both in the fetus and in its surroundings, and the bearing of these details of development on problems of pathological interest, are matters that are being gradually realized within the medical profession. What is not realized, perhaps, is the possible greatness of the importance. The ordinary courses in embryology which are prescribed for the student would be laughable in their inadequacy if it were not that they give him, at any rate, reason for knowing that the human body is not a performed thing, fixed from the beginning, but must bear within itself certain inherited qualities and their stigmata, so that when he has to consider some pathological problem he may perchance remember that there are other questions behind those arising in the postmortem room and pathological laboratory, and this may lead him to seek for authoritative information about them. It is here, unfortunately, that he is very likely to find himself at a loss. There are problems in development that have never been touched and others that have hardly been considered at all. Human organogeny has been worked out with fair accuracy and completeness in its broader aspects, but the finer points and the interplay of factors in the production of results, and the nature of the factors themselves, are still to be done, and it is here rather than in the larger matters that pathology will be looking for help.

To give a simple example of the differences referred to, the known stages of formation of the palate afford an explanation of the anatomical situation of the fissure, but not of the cause of a cleft palate. Here we want information on the factors which cause full growth of the maxillary process and on the causes of its failure in growth, and about these we know nothing. Such matters, more abstract and intricate, which do not come within the purview of the ordinary student, can only be slowly solved by those who devote their time to research of this sort, and they must depend for their material on the clinician, who alone is in the way of obtaining it. Embryologists can obtain specimens at all stages from most animals, but for human embryos they are forced to rely on the help of their practising colleagues. Much of the material procured in this way is abnormal, but that need not deter the practitioner from sending it, for the skilled study of abnormal formations may often throw light on dark places; it is of much more importance that its histological characters are fairly good, whence the attention to preservation asked for in the letter. The study of human embryology in England has hitherto depended on the use of private collections, and it is well to aim at the formation of a large and representative gathering of specimens, in which the help of the practitioner is essential, and surely will not be withheld.—*The Lancet,* January 2, 1926.

Child Marriages in New York State.—Child marriages have assumed the status of a "problem" in the last few years. While in New York the statutory age for marriage is eighteen for women and twenty-one for men, in 1922, the last year for which figures are available, there were solemnized in the State, exclusive of New York City, 172 marriages in which the bride was fifteen years of age or less and 74 marriages in which the groom was seventeen years of age or less. There were 634 brides sixteen years of age and 1,365 brides seventeen years of age. Sixty per cent. of these child-brides came from the rural sections of the State.

New York State is one of the fourteen states in the Union in which, with the consent of the parents, boys and girls *of any age* may legally marry.

At the request of the State Child Welfare Commission a bill has been introduced in the Legislature to amend the domestic relations law under which applicants for marriage, if under sixteen years of age, must have the written consent of the judge of the children's court, or, if there is no such court, of the county surrogate.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

Physicians in Congress.—The Congress of the United States is made up of ninety-six Senators and 435 members of the House of Representatives. About two thirds of these congressmen are lawyers or have had legal training. The remainder are mostly business men, farmers and publishers, with a sprinkling of educators and engineers. Only six are physicians, five of whom are members of the House. There are three dentists, two of whom are in the House. In previous Congresses the number of physicians has been slightly greater, though the profession has never been well represented at the capitol. The only physician in the Senate is Royal S. Copeland, democrat, New York, who was health commissioner of New York City. He has served as vice-president of the American Public Health Association. The dentist in the Senate is Henrik Shipstead, Farmer-Labor, Minnesota. Two other Senators, Woodbridge N. Ferris, Democrat, Michigan, and George H. Moses, Republican, New Hampshire, studied medicine for brief periods. Three of the physicians in the House are Republicans and two are Democrats. Three were in active practice when elected, while one was engaged in farming; the other, who is also a lawyer, was specializing in legal medicine and the practice of law. Dr. E. M. Irwin, Republican, Belleville, Ill., graduated from Missouri Medical College of St. Louis and practiced from 1892 until elected to the Sixty-ninth Congress. Dr. Ladislas Lazaro, Democrat, Washington, La., has been a member of the last seven Congresses. He was educated at Holy Cross College, New Orleans, and graduated in medicine in 1894, having been in active practice until 1913. Dr. John J. Kindred, Democrat, Astoria, N. Y., studied medicine at the University of Virginia and Hospital College of Medicine of Louisville, Ky., from which he took his M.D. degree in 1889. He is also a law graduate and has lectured on medical jurisprudence and is especially interested in mental disease. He served in the Sixty-second Congress and from the Sixty-seventh to date. Dr. William T. Fitzgerald, Republican, Greenville, Ohio, graduated from Wooster University Medical School and practiced until elected to the Sixty-ninth Congress. Dr. John W. Summers, Republican, Walla Walla, Wash., engaged in the practice of medicine for twenty-five years after graduating from the Kentucky School of Medicine and the Louisville Medical College. He has been in Congress since the Sixty-seventh Congress. The two dentists in the House are Dr. Roy O. Woodruff, Republican, Bay City, Mich., and Dr. Frank Crowther, Republican, Schenectady, N. Y. Both have served in a number of Congresses. Although these physicians and dentists are the only representatives of their professions in Congress, the biographic sketches of some other members, as given in the Congressional Directory, reveal an interest in public health and medical matters. Thus Mr. Robert G. Houston, a lawyer, Republican, Delaware, was a member of the first state antituberculosis commission and is now vice-chairman of the commission for the feebleminded, while Representatives Louis A. Frothingham, Massachusetts, Ernest R. Ackerman, New Jersey, and John M. Morin, Pennsylvania, are trustees of various hospitals.—*Journal American Medical Association,* February 13, 1926.

Miscellany.

The Revolution Neurosis (Pregnant Women and the Scaffold).—*The Revolution Neurosis,* which Dr. Cabanès and Dr. L. Nass published several years ago, for which Jules Claretie wrote a curious preface in which one can guess his embarrassment in praising without restriction this interesting research into the troubles of the revolutionary movement, has been for some time out of print. Now a new edition, revised and considerably enlarged, is available. It will give an opportunity to those who do not yet know it of reading this work consecrated to the psychopathological crisis that attended the revolution of '89 and which explains in part the terrible deeds that our ancestors witnessed, even the sinister nature of Fouquier-Tinville, who sent to the scaffold pregnant women just as a butcher slaughters a cow with calf to "destroy the species." "If a woman condemned to death declares herself pregnant," says a criminal edict of 1670, "she may suffer her punishment after deliverance." The Revolution granted this same privilege. But the Terror disavowed these principles of humanity and justice, and the guillotine made no difference between the woman and the child, between the maiden and the future mother; all were equal under the axe. It was to the Hospice de l'Evêché, a sort of infirmary prison, that were generally sent women held in the various prisons of Paris who declared themselves pregnant. There the physicians of the hospice, assisted by a midwife, citizeness Prioux, drew up a report based on their visits, which was submitted to the public attorney who pronounced the final verdict. If favorable this amounted only to a reprieve; after accouchement, execution was decreed. But usually Fouquier-Tinville paid no attention to these reports of the doctors. This was one of the principal accusations against Fouquier when he appeared before the revolutionary tribunal—that he sent to the scaffold women who were declared to be pregnant and upon whom the physicians had pronounced their decissions. Many women, in the hope of obtaining a reprieve, declared themselves about to become mothers in the hope of prolonging their lives for a single day.—*Translated from Æsculape.*

Body Health and Physiognomy.—Dr. Löwenstein, of Hanover, recently demonstrated, by the aid of portraits and diagrams, the connection between body build and physiognomy. In the study of abnormal mental manifestations, psychiatrists no longer confine themselves to observation of the brain and skull formation, but study the form and structure of the whole body and the face which may give important information. Kretschmer, of Tübingen, has distinguished three different types of body build, 1, the slender, with small head, slender neck and sunken chest; 2, the athletes, with broad chest and great muscular development, and 3, the thickset, with compact body build, short legs, protruding paunch, head thrown forward, a rounded back and usually a heavy beard. The two former have, more or less, the same temperament, and if affected by mental disease, the intellectual centres are attacked. In the third group only periodical depression occurs, and the intellectual centres are not affected. A temperamental character is to be observed even in subjects who are mentally sound. Those of the two former groups seek retirement, their actions are usually characterized by pronounced egoism, by reason of which their own personality becomes the centre of every interest. They include the great systematic thinkers. The third group are not given to systematic logical thinking, and possess a vein of humor; they give evidence of an altruistic character. Kretschmer appears to have made his deductions from the male sex alone, but English observers have found the body build of females is the truer index to types of temperament.—*Medical Press and Circular,* January 13, 1926.

Impressions of Ophthalmological Activities Abroad.—John E. Weeks describes in *Northwest Medicine* for February, 1925, the operations for cataract watched in France, Switzerland, Spain, Egypt, Ceylon, India, Burmah, Siam, China, and Japan, and concludes with the following remarks:

The variations in technic adopted by various able men illustrate the individual variation in adaptability. There are probably no two operators whose technic is exactly the same. Because of these facts we should be slow to denounce the claims of any able man regarding the good results obtained by any form of technic that he may employ. There is one point in the technic that is now very generally adopted, namely, in regard to the site of the incision. By far the greater number of surgeons make the incision for the removal of cataract in vascular tissue at or just back of its limbus. My experience has led me to believe that down growth of epithelium into the anterior chamber does not occur when the incision is made in vascular tissue.

Stammering and Stuttering from the Medical Viewpoint.—May Kirk Scripture and John A. Glassburg (*Archives of Pediatrics,* August, 1925) state that the treatment of speech disorders is primarily a medical problem and then an educational one. The best form of therapy is that under a medical speech specialist well versed in neuropsychiatry, psychology, rhinolaryngology and phonetics.

Many behavioristic attitudes are caused by speech disorders. Among them are mental retardation, feeblemindedness, inferiority complexes, shutin personalities, shyness, timidity, maladjustment, suicidal tendencies, emotional insanity, criminality and other antisocial characteristics.

Stuttering and stammering are distinct speech disorders. The former is difficult speech and the latter incorrect speech or mispronunciation. The cause of stuttering is subject to much controversy. The authors find it to be an underlying neuropathic predisposition and exciting cause which is in the nature of a nervous shock.

Stammering is for the most part a speech disorder due to a rhinolaryngological defect, which may be adenoids, abnormal length and thickness of the uvula, abnormal size and tumors of the tongue, hemiatrophy of the tongue, cleft palate, harelip, deformities of the jaws, improper development of the palatal arch, intranasal obstructions, tongue tie or defective hearing. The treatment in every case of stammering is, first, removal of the rhinolaryngological abnormality and then proper breathing exercises, correction of the bad speech habits, and phonetic reeducation.

International Medical Stations for Sailors.—Norway has set up twenty-one medical stations for sailors of all nations in her seaport towns. The step is the first in a much wider scheme propounded by the Norwegian Red Cross to the General Council of the League of Red Cross Societies. If it is carried out all the seafaring members among the fifty or so nations represented on the council will follow Norway's example and linked Red Cross medical stations will be available for the sailor throughout all ports of the world. The advantage to him and to his fellows is obvious. He is notoriously careless of his health. If he seeks advice in port he falls as often as not into the hands of quacks and sharks. Frequently ailments which if recognized in time might be remedied go untended, to the patient's and to the general danger; and this in spite of the very great improvements that recent years have seen in the general conditions of life at sea. Mr. Masefield's plaint of the sailor racked with fever smacks no doubt of the bad old days, but who dare say the lines have no application now? "Now them there passengers," he said, "if they gets fever chills, there's buckets of quinine for them 'n' bulgin' crates o' pills, 'N' a doctor with Latin 'n' drugs 'n' all—enough to sink a town, 'N' they lies quiet in their blushin' bunks 'n' mops their gruel down. But there ain't none o' them fine ways for us poor sailor men." The lot of the tramp sailor, dependent on the stock medicine chest and the captain's skill in using it, is no great advance on this even yet; and a plan which would ensure him the best advice and continuous treatment from port to port at a small fee—for there is very properly no suggestion that the plan should be charitable—deserves that serious consideration of the maritime members of the Red Cross for which Dr. Harald Engelsen, who pioneered the Norwegian plan, pleads in the current number of the *World's Health.—Manchester Guardian Weekly.*

Leprosy in India.—A report of the year's work in India of the Mission to Lepers shows that not only is the relief of those afflicted with this disease still left to charity without State assistance, but that the Indian Mission is supported in far the greater part by private subscriptions from other countries, says the *Medical Press and Circular* January 13, 1926. Barely one sixth of these are contributed in India. Besides the care of those disabled by leprosy and the deformities resulting from it, the Mission undertakes the charge of the untainted children of those so suffering. From the findings of a medical subcommittee which met in 1924, at Allahabad, it is evident that leprosy can eventually be eliminated; for it has been proved that, in its early stages, it is not infectious and is highly amenable to treatment. It is not congenital, but infancy is the period during which it is most likely to be contracted; and as the disease progresses it may become so dangerously infective as to make segregation imperative. It is well that these facts should be widely known, so that patients, recognizing the first signs and symptoms of the disease, may be encouraged to report themselves and undergo the necessary treatment. The success of the measures recently adopted for the cure of leprosy calls for the assistance of the State in devising and supporting measures for combating its spread and procuring its eventual eradication.

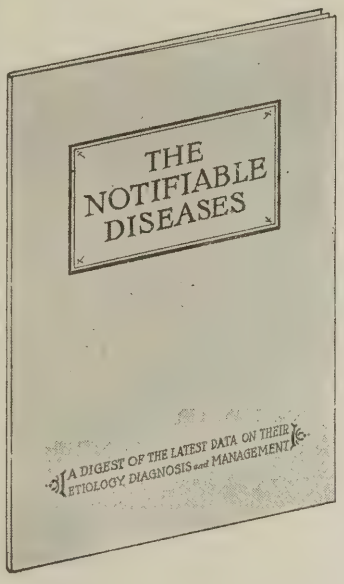
Siebentes Heft, Verletzungen und chirurgische Krankheiten der Mund-und Rachenhöhle, des Halses, etc. Von Prof. Dr. Paul Clairmont. Mit 97 Textabbildungen. Leipzig: Georg Thieme, 1926. Pp. 188.

The Notifiable Diseases



Their etiology, transmission, incubation period, diagnosis, duration, quarantine restrictions, and terminal disinfection.

Prepared under expert supervision, this timely booklet has been especially arranged to furnish the busy practitioner with a wealth of condensed information concerning the contagious diseases, that he cannot obtain elsewhere except at the cost of much time and effort.

If you would like to have a copy of this remarkably useful and attractively printed booklet, send in your request today with your professional card, and it will be sent free of all expense, by return mail.

If you wish to test **Gray's Glycerine Tonic Comp.** in some case of debility, malnutrition or convalescence after Grippe, Measles, Scarlet Fever and so on, a liberal sample is at your service.

Valentine's Meat-Juice

For **Quieting** the **Irritable Stomach, Aiding Digestion** and **Sustaining** and **Strengthening, Valentine's Meat-Juice** is employed in Hospital and Private Practice in the treatment of

Diseases of Children.

W. B. Scranton, M. D., *Medical Superintendent, Korean Mission Methodist Episcopal Church, Seoul, Korea:* "A most excellent use I frequently put VALENTINE'S MEAT-JUICE to is tiding Babies through Cholera Morbus and the Wasting Diseases incident to Summer and Inanition. It acts at once, and many a crisis has been passed safely by my patients, through the agency of VALENTINE'S MEAT-JUICE. It has also been of great value in my practice in the Far East in the treatment of that form of Summer Diarrhoea known as Sprue, where it tides the patients over until they can get to a better climate, and the change of climate rectifies the rest."

VALENTINE'S
PREPARATION
NUTRIO
PER ML
VOLUME 1 4/5 OZ.
MEAT JUICE.
The result of an Original Process of preparing Meat and extracting its Juice by which the elements of nutrition are obtained in a State ready for immediate absorption.
DIRECTIONS. Dissolve one teaspoonful of the Preparation in three tablespoonfuls of cold or warm water, boiling water changes the character of the preparation

For Sale by American and European Chemists and Druggists.

Miscellany.

British Scientists Plan Science News Service.—A British *Science Service* is now being planned by a committee of scientists appointed by a conference of representatives of leading British scientific and technical organizations. The British Association for the Advancement of Science and the British Science Guild joined in calling the conference to consider the advisability of establishing a news service to popularize science for the English newspapers and their readers. Resolutions were adopted approving the idea and the committee now at work was asked to recommend methods and organization. Sir Richard Gregory, editor of *Nature,* the leading scientific magazine of England, is chairman of the committee.

Encouraged by the success of *Science Service* in America, those sponsoring the project feel convinced that there is a place in British science and journalism for a similar organization to furnish authentic, yet interesting scientific news to the press. They realize, however, that there are problems peculiar to English journalism that must be met.

The organizing committee has been assured of the close cooperation of the American *Science Service,* now five years old, but the American organization, while cooperating and exchanging news, will have no financial interest in the new British organization. The movement for a British *Science Service* was inaugurated at a luncheon tendered by American *Science Service* to leading scientists at the Southampton meeting of the British Association for the Advancement of Science last August.—*Science Service.*

The Early History of Aeronautics.—At a meeting of the Royal Society of Medicine held on February 1st, Dr. F. J. Poynton gave an address on the Part Taken by Doctors in the Early Days of Aeronautics. He traced men's intereset in aerial flight back to the earliest recorded times. In the *Book of the Dead,* he pointed out, the spirits were shown winged, and there were many stories of men aspiring to the sky drawn by eagles or with wings. The earliest illustration was found in a wood cut of Dædalus and Icarus, published in 1493. Turning to the particular history of the lighter than air machine, the lecturer drew attention to the many celebrated names associated with it. Roger Bacon, Montanus, Leonardo da Vinci, Robert Hook, Cavarro, Swedenborg, Lavoisier, and Priestley had all been bitten by the craze, but, as so often happened, the solution of the problem came from an unexpected source. In 1782 the two brothers Montgolfier first saw a paper sphere filled with heated air float to the ceiling of their room. They gave their first public demonstration in the following year, when a sphere with a capacity of sixty-five cubic feet was successfully floated with heated air. The importance of their success was realized at once. Two and a half months later hydrogen was first used by Mr. Charles to inflate a balloon of such dimensions that 1125 pounds of iron and 560 pounds of sulphuric acid were required to supply it. Fierce controversy ensued as to which of the two methods was the better.

Later, in 1783, a cage balloon carrying a sheep, a duck, and a cock were sent up in the presence of the King, the Queen (Marie Antoinette), and a large and distinguished crowd. Among them were Marat, who was much interested in aeronautcis; Mr. Charles, who was afterwards saved from the guillotine by his eloquent address to the crowd, in which he recalled his aerial experiments and the popular enthusiasm they aroused; and the famous de Rozier, who began life as a medical student at Metz, but turned to science to escape the ordeal of anatomy. He became director of the first science museum in Paris, and in 1783 made an aerial journey across Paris. Benjamin Franklin was the link between these Parisian ventures and England, through his correspondence with Sir Joseph Banks, in the course of which he wrote: "Your philosophy seems to be too bashful; in this country we are not so ashamed of being laughed at." But it was not long before the "balloon madness" of Paris, with its caricatures, toy balloons, stamped handkerchiefs, and even garters, spread to London, and in September, 1783, a balloon was sent up from the Artillery Ground. On February 2, 1784, a five foot balloon let free at Sandwich floated across to Flanders, and was the first to cross the Channel. In Scotland the versatile and ill fated Dr. Tytler made an ascent in a hot air balloon on August 25th, but returned to earth with some precipitancy. His later attempts failed. In 1784 the Italian Lunardi arrived in London with letters of introduction to Banks and others, and in September made an ascent in a gas balloon which was filled for the occasion by Dr. George Fordyce, of St. Thomas's Hospital. Among the spectators on that occasion were Mr. John Sheldon, F.R.S., of Paris, surgeon to the Westminster Infirmary; Dr. Jeffries, a Boston physician practising in London; and the Frenchman, Blanchard. These three were the pioneers of early English attempts to fly. The first woman to make an aerial journey was Lunardi's friend, Mrs. Sage. On both sides of the Channel feverish preparations were being made to cross the water, and after several difficulties Blanchard and Jeffries succeeded in doing so on January 7, 1785, after a journey of two hours and forty-seven minutes. De Rozier's effort from Boulogne resulted in the balloon crashing on French soil and killing both him and his companion, de Romain.—*Lancet,* February 6, 1926.

Women Flyers.—In the opinion of Major Oliver Stewart the medical tests, which are being carried out by the Air Ministry to ascertain if women are physically and temperamentally fit to fly, are unnecessary. He asserts categorically that women are not fit to pilot passenger carrying aeroplanes, and the reason he gives will surprise many. It is that they are much too fearless: "The fearless pilot is almost invariably a bad pilot. Fear is the best of flying instructors, for it teaches its pupils what not to do, and it warns them in a memorable manner what will happen if they disobey. Women are without this instructor; they do not know physical fear. The typical Englishwoman, who is sufficiently courageous to play furious football, and hic, hac, hockey, to fight for 'buses, to wear 'sensible' clothes in Paris, this woman, I say, should not be allowed with a blunt penknife in her hand, much less with the control stick of an aeroplane."—*Medical Press and Circular,* March 24, 1926.

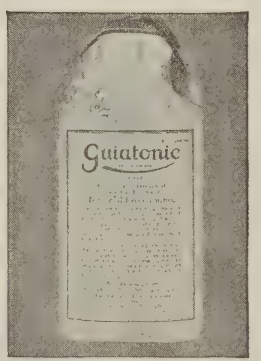
"Residual Infections"

after the acute respiratory diseases, are often found in the tonsils, sinuses, lymph glands and other focal points. These groups of germs lie hidden until some condition arises that permits them to re-attack the tissues, and bring on a recurrence or complication. To cope with these residual infections, Guiatonic has proven itself a worthy and dependable ally. Given as soon as an acute respiratory infection develops, it stimulates and supplements the natural bactericidal, defensive and recuperative forces of the body, thus supplying the aid so generally needed to counteract the attacks of lurking germs —and restore bodily health and resistance.



A palatable preparation of guaiacol and creosote which may be freely given to the weakest patient, without fear of gastric disturbance. *It contains no narcotics.*

Indicated in all depressed or debilitated conditions, or whenever a tonic is required.

Guiatonic

A liberal supply for testing free to physicians. William R. Warner & Company, Inc. Manufacturing Pharmaceutists since 1856. 113-123 West 18th Street, New York City.

Medical Practice in China.—The status of qualified medical men in China, whether missionaries or otherwise, is likely to be very uncertain if the rights which they have enjoyed as foreigners should be abolished, says the *Lancet* for February 6, 1926. At present no protection is afforded them comparable to that which the profession has in England, America, and elsewhere. If a doctor in China has no status from a treaty he may be sued in a Chinese court and have to meet very heavy claims for damages, as was illustrated quite recently when a German doctor lost a patient after an operation and had to pay $3000 damages. The Chinese custom of paying the doctor as long as the family is in health need not complicate the situation, for after all it is but an illustration of contract practice, but the immediate difficulty is that there is no sort of medical registration. People with the most rudimentary knowledge —embryonic medical students or even hospital coolies —frequently set up in practice on their own, and such organizations as the China Medical Association and the China Medical Missionary Association are quite unable to control the unqualified practitioners. If no protection for medical men is arranged at the Extra-Territorial Conference their work in the future will be carried on with great risk and difficulty. If failure leads to financial disaster it may be supposed that only simple cases will be undertaken. There is little reason to think, however, that the Chinese Government would not welcome, in the interests of the medical profession among its own nationals, the setting up of a register of properly qualified medical men. Perhaps the plan followed by the Japanese when they took over Korea may be adopted. At first they had to recognize the existing native practitioners and doctors holding British degrees (these are still recognized). Only a five years' recognition within a limited area was granted to a large number of American doctors, but after the matter had been taken up diplomatically those who were already at work in Korea were given full permission to practice. Since then every newcomer from America has had to take a Japanese medical examination, and though an elaborate system of certificates and reports has been instituted, the net result, it is said, has been to the advantage of medical standards.

New Zealand and Endemic Goitre.—Since New Zealand has no inhabited locality more than a hundred miles from the sea, immunity from goitre might be expected; but an exhaustive study by Hercus, Benson and Carter, of the University of Otago, has disclosed a widespread prevalence. Thirty-one per cent. of school children are affected, and in some areas as many as sixty per cent. show thyroid enlargement. The Maoris are by no means immune. The incidence of goitre is generally in inverse proportion to the amount of iodine in the soil, and thus to the amount contained in the food supply of the population. In some districts, however, the iodine appears to be derived from the drinking water rather than the food. Statistics show that of the male conscripts between twenty and forty-five years of age examined by military medical boards during the war, almost one per cent. was declared unfit for active service on account of thyroid enlargement.—*Medical Press and Circular,* April 21, 1926.

Noise and Fatigue.—Eliminate noise and eliminate fatigue could well be the slogan of practically all human activities, says *Nation's Health* for March, 1926. Industry, the city, the home, all contribute their quota to the overproduction of these harmful and useless accessories of present day civilization. Primitive people are quiet people, and indulge in noise and noise making only on special occasions when it is desired to arouse to some unusual pitch the emotions of the clan.

Physiologists agree that noise is fatiguing, although there seems to be a socalled aural tolerance which is acquired, but not to the same extent, by all persons. Irreparable deafness results from too long exposure to certain noises, as is seen in boilermakers and others following similar occupations. The relation between noise and industrial fatigue has been studied sufficiently to determine that one has a direct bearing upon the other.

While the average person can adjust his nervous system to many noises without apparent harm, the more subtle effects cannot be measured. Inability to concentrate the mind, to plan activities, to meet sudden mental emergencies is often noted in a noisy environment. The effect of noise in retarding recovery from illness has long been recognized, but measures for its control have not been so effectively put into play. Reduction in noise both within and without the hospital by means of noiseless flooring and street paving will do much to make the life of the patient more bearable and comfortable.

Noises in and near schools are distracting and interfere with studies. The double strain of noise and study is harmful to the growing child and doubtless lays the foundation for disorders of the nervous system later in life.

Research has enabled engineers to choose effective sound absorbing materials to prevent the passage of sound and satisfactory acoustical correction installations to reduce the reverberation of sound within rooms. While the use of such materials may involve an increased construction expense, this will be offset by favorable returns in many other ways.

Noise is a public health problem of no mean proportions, and it merits the careful consideration of health officers in their programs of health betterment. It is physiologically, economically, and socially desirable to reduce it to the lowest possible minimum.

Yellowstone Park Has New Hot Spring.—A new hot spring has broken out at Mammoth Hot Springs, where the park headquarters are situated, according to a report from Park Naturalist E. J. Sawyer. The new jet comes through a vent about two inches long and three quarters of an inch across, and is depositing travertine limestone over an area varying from twenty-five to thirty-five feet in diameter. It is located in the lower part of the great group of limestone terraces, near the rocky cone known as Liberty Cap. Due to the soft and crumbling nature of the limestone in the Mammoth Hot Springs formation, there is a good deal of shifting about in the location of the springs in this place, but there has been no activity in this particular section of the formation for twenty years or more.—*Science Service.*

Miscellany.

Building Insulation and Health.—Winter months are shutin months and with the great range in climatic conditions to which the average person is subjected—from the tropical dry heat of many buildings to zero temperature out of doors—a terrific strain is placed upon the body heat regulating mechanism. The increase of respiratory diseases is more or less directly connected with this situation.

Another important cause of ill health, particularly in rural schools and similar buildings, is the great variation in temperature within a given room. While those near the heat source—usually a stove—are too warm, those in other parts of the room are in an atmosphere many degrees colder. Such situations can be greatly improved by the application of a little knowledge of physics at the time of construction, or in buildings already in use. By the utilization of proper insulating materials, heat can be conserved and more evenly distributed, and cold can be excluded. The old frame schoolhouse in which the children either roasted or froze, depending on their location in the room, should give way to the modern building with heat properly conserved and distributed.

Of major interest, if not of equal importance, is the provision for exclusion of summer heat, particularly in sleeping and resting quarters. In poorly constructed buildings such rooms reach a high temperature during the day which is not reduced at night as much as is the surrounding oudtdoor temperature. This condition makes for restless sleep with its lack of recuperation. Heat can be excluded as well as conserved, proper building construction serving both purposes.

By the prevention of minor colds prolonged illnesses of a more serious character are prevented. Proper environment for rest is equally essential. Health education in the schools cannot bring the desired results unless, by example, the pupils are taught something about proper heating and ventilation. These are problems with which the health officer should concern himself, for they have a direct bearing on the health and comfort of large numbers of people.—*Nation's Health.*

School Rooms Badly Lighted.—The lighting of school rooms in the United States, especially the provision made for artificial lighting, is far below the standards considered economical by up to date business establishments, according to E. J. Dailey, Jr., illumination expert of New York, who attended the National Education Association meeting. "Wisconsin is one of the very few states that has a lighting code controlling the standard of lighting for school buildings," said Mr. Dailey. "If more states would enact a similar code many of the present evils would be eliminated. Investigations have shown that healthy eyes, under normal conditions, use up from 10 to 15 per cent. of the whole nerve force generated by the body, but the eyes may use up as much as 50 per cent. of this force if subjected to undue strain. Other studies have shown that at least one fourth of our school children have defective vision, and much of the trouble can be traced to improper lighting either in the school or in the home."—*Science Serivce.*

Why Are Gum Infections So Common?

100% of toothbrushes in use we have had examined showed staphylococci of various kinds; 40% of the same brushes showed hemolytic and non-hemolytic streptococci; 15% showed pneumococci. All showed food particles though washed under the tap before examination. Some of the brushes belonged to Physicians. We can hardly hope for fewer cases of gum infection and diseases resulting therefrom, so long as we continue to use a septic instrument, the bristles of which frequently prick or scratch the gum tissue.

RE VIRA

provides a new pad for each cleaning of the teeth and massaging of the gums. Nurses find it ideal for cleaning the tongue of the sick.

Pads are used dry or slightly moistened between the teeth first, then over each tooth and gum, and finally wet like an ordinary brush. Dental tape should be used every night before retiring.

Re Vira outfits consist of holder and box of refill pads. Adults $1. Childs $0.75.

The Evolution of Man's Brain.—Much the most remarkable instance in the biological world of steady development in one direction has been the evolution of the human cortex cerebri from the earliest mammalian phase of Man's ancestry. This evolution, which has occupied several millions of years, has been in one definite direction—that of increasing intelligence. Here we have an instance—a supreme instance—of apparent orthogenesis—the tendency of an organ to vary progressively in a definite direction. When, however, we come to examine into the circumstances under which this evolution has taken place, we find no evidence of an innate tendency to mental advance. All evidence points to the conclusion that Man's mental evolution has been effected by changing conditions of life of a kind calculated to confer survival value on intelligence above the mean of the species.

The fact that the extant anthropoids have remained on much the same level of intelligence during the period of the evolving man has nearly, if not quite, trebled his cerebral cortex, conclusively shows that cerebral evolution is not the outcome of innate tendency.

The abandonment of forestrial life for the life of the hunter greatly increased the survival value of superaverage intelligence, and it was this change in the conditions of life which enabled the evolving man to outdistance his competitors in the race for mental supremacy.—*Medical Press and Circular*, March 3, 1926.

Five Greatest Contributors to Medical Progress.—In response to an invitation by the *Medical Press and Circular* for the comments and criticism of its readers, that journal received and published letters from several representative authorities on the history of medicine in England. Had any replies come from foreign countries we should have been prepared to find that they revealed further diversity of opinion: for there can be no doubt that the literature and teaching of each nation is imbued with some degree of bias, similar to that discovered in the answers of the American students. The five names suggested by the *Medical Press and Circular* were accepted with slight difference by most of the correspondents; and the selection of those who limited themselves to five names show the following result:—Harvey ten, Hippocrates nine, Sydenham eight, Pasteur eight, John Hunter five, Galen three, Vesalius two, and Celsus, Leonardo da Vinci, Morgagni, Laënnec and Lister one each. In some instances there was doubt between Sydenham and Laënnec, and between Sydenham and Boerhaäve; and in others between Lister and Hunter, and Lister and Pasteur.

In the matter of Galen the plea is made that, of the earliest contributors, he alone is known to us personally, and that the legendary character of Hippocrates suffices to give Galen the preference. From this aspect the selection may be justified, but the substitution does not appeal to us. "Pass the name of Galen," says one correspondent. "Was not his system the whole science and art of medicine for well nigh fifteen centuries? Were not his utterances as the words of Holy Writ? Was not his the textbook of medicine until the seventeenth century?" Granted that it was not his fault that the standard he had set was not surpassed by many subsequent generations: but it cannot be denied that those generations were enveloped in a darkness which was only illumined by the renaissance of medicine initiated in the sixteenth and completed in the seventeenth century by Harvey's discovery, which prepared the way for the work of Glisson and Sydenham and the further discoveries of Pecquet, Rudbeck, and Mayow. Medieval darkness alone enabled the Galenic system to uphold its supremacy so long.

By some John Hunter was omitted from the "Big Five"; but the journal remained firm in its choice. The contributions of John Hunter to the progress of medical science and medical research are still inadequately understood by the majority. "John Hunter formed the superb conception of merging into one both classes of ideas—the normal and the abnormal in nature—by showing that nothing is irregular, nothing perturbed, nothing disobedient. Centuries perhaps may elapse before that conception will be consummated. But what Hunter effected towards it places him at the head of all pathologists, ancient or modern. For with him the science of pathology did not mean the laws of disease in man alone, or even in all animals, or even in the whole organic kingdom; but it meant the laws of disease and of malformation in the entire material world, organic and inorganic. His great idea was to raise a science of the abnormal." Of those who are able to realize what pathology was when he found it and what it was when he left it, there will be few to deny that John Hunter revolutionized medical thought and the medical outlook more than anyone, with the exceptions of Harvey and Pasteur. Upon the shoulders of these three men, to borrow a well turned phrase, stands modern medical science.

Women's Fingers Work Faster Than Men's.—A method of measuring the speed in an individual's fingers has been devised. The test has been applied to 1,021 women applying for work in the shops of an electrical company and the results are described in a recent issue of the *Journal of Personnel Research* by Mildred Hines and Johnson O'Connor. The equipment used by the experimenters consisted of nothing more than three hundred brass pins and a flat metal plate in which one hundred holes were drilled part way through. Candidates for work requiring agile fingers are asked to pick the pins from a tray in which they are piled loosely and to place three pins in each drilled hole in the plate as rapidly as possible. They are instructed to try to pick up the pins three at a time in order to make maximum speed. Individuals vary widely in this test. The fastest finish in less than six minutes and the slowest require from twelve to fifteen minutes. Since the inauguration of this test seventy-seven new women workers have been assigned to the fine meter or instrument work requiring finger dexterity. Subsequent records show that more than eighty-five per cent. of these women are successful in the work. The test also showed that women are much better adapted for this work than are men. The test is said to eliminate much of the guess work and personal equation factor in the hiring of workers for this type of work.—*Science Service.*

Treating Hypertension and Arteriosclerosis

A New Method

ANIMASA

Registered Trade Mark

An Organic Preparation

Therapeutic Indications
Arteriosclerosis
Hypertonus
Nephrosis with Hypertonus

No Injections
No Reactions
Dose
1 to 3 tablets t. i. d.

Composition Properties
Desensitization
Blood Pressure Reducing
No Vasodilators Present
Organotropic

Animasa is endorsed and used by medical authorities of International reputation among whom are:

PROFESSOR LEWIN
University of Berlin

PROFESSOR MATTHES
University Königsberg

CAPROKOL

(HEXYLRESORCINOL S & D.)

$C_6H_3(OH)_2C_6H_{13}$

Indicated in treatment of infections of the urinary tract.
Approximately 45 times the germicidal power of Phenol.
Non-toxic in therapeutic doses.
Renders the urine germicidal.

FOR ADULTS:—Soluble Elastic Capsules CAPROKOL (Hexylresorcinol, S & D.)
FOR CHILDREN:—Solution CAPROKOL (Hexylresorcinol, S & D.)

Ethics in Advertising.—A single issue of a prominent and reputable Boston newspaper was recently found by the *Boston Medical and Surgical Journal* to contain the following advertisements:

1. A pill that cures constipation, biliousness, belching and acid risings in the mouth. 2. An application that relieves lumbago, neuritis, sciatica, colds and every ache and pain. 3. A preventive of tonsillitis that kills germs without injury to the delicate throat membrane. 4. An external remedy that relieves colds without dosing. 5. An ointment that positively stops any case of itching, blind, bleeding or protruding piles. 6. A headache cure. 7. An internal remedy to reduce fat. 8. A chewing gum that safely takes off fat at the rate of several pounds a week. 9. Bitters that make rich blood. 10. Pleasand little tablets that are better than calomel. (No need to question this.) 11. A complete cure of rupture without operation, after trusses had failed. 12. A safe and proven remedy for colds, grip or influenza. 13. Another fat reducing gum.

The *Journal* comments as follows: "It is not through the substances themselves that their greatest harm is done, however. The chief objection to all of them is that they furnish either symptomatic or psychic relief and may, and probably do, often act tragically to the disadvantage of their users by masking symptoms of grave disorders. A fire department that considered it its main duty to prevent the escape of smoke without hunting for the blaze would not long be countenanced in a really up to date community."

Indentured Children.—Indentured children in Wisconsin, one of the twelve states permitting such indenture, have been studied by the Children's Bureau at the request of Wisconsin authorities. The homes provided for a large proportion of the 827 children studied, who were indentured on written contracts by the State Public Scholo at Sparta, Wisconsin, under a law enacted in 1885, were in many cases actually detrimental to the children. Many of the children, the Bureau found, worked virtually as unpaid servants in households or on farms, often deprived of schooling and recreation and sometimes cruelly treated. Five hundred and forty indenture homes in many parts of the state were visited by the Children's Bureau investigators, who, after very careful and conservative weighing of the facts, judged forty-eight per cent. of the homes as actually detrimental to the children, forty-four per cent. as satisfactory, and only eight per cent. as high grade.

The children were usually committed because of neglect, abandonment, the poverty or the immorality of the parents, by county poor commissioners or judges, who were not equipped to investigate the cases or to apply measures for rehabilitating homes or for keeping the families together. When committed, the children were sent to the State Public School and were then indentured or placed out for adoption with little or no attempt to find the home that best met the needs of the child. Supervision after placement was inadequate, with only two agents to guard the welfare of the approximately five hundred children scattered throughout the state, so that the children might, and in some cases did, wait months or years for a chance to complain to the agent of cruelty or overwork.

The Children's Bureau study was completed, so far as the gathering of facts was concerned, in 1923. Wisconsin authorities have notified the Bureau that some improvements have been made. The law is still the same as in 1923, however, and, according to the director of the juvenile division of the state board of control, sufficient appropriations have not yet been made to supply an adequate staff at the State Public School. Recommendations of the Children's Bureau include abolition of indenture, a program for the prevention of child dependency and the breakup of homes, careful study of the individual child, and better investigation and supervision of homes in which children are placed.

Fewer People Die of "Old Age."—Forty years ago, almost five thousand deaths in New York State were attributed to "old age." Last year the number of deaths so classified was only 610, a decrease of almost ninety per cent. The number of deaths from all causes increased seventy-five per cent. in this period. What is the reason for the astonishing decrease in mortality from "old age"? Most of these deaths fall in the age group "seventy years and over," although some deaths are attributed to senility at earlier ages, occasionally even in early middle life. The population of the State has doubled and the number of old people has more than doubled since 1885. The decrease in the number of deaths from old age is, therefore, not due to a shrinking in the contingent of the population from which these deaths are drawn. The reason for this change lies in the more careful and scientific diagnosis of the cause of death. Where forty years ago, the death of an old person, because of indifferent reporting or for want of knowledge, was often attributed simply to the effects of old age, now an effort is made to establish a definite diagnosis in every case. The progressive reduction in deaths under this head marks the growing skill and attention on the part of the practicing physicians of the State.

Stale Chlorinated Lime Ineffective as Germicide.—Chlorinated lime, also known as bleaching powder, and sometimes incorrectly called chloride of lime, a substance used extensively as a germicide, deodorant, and bleaching agent, loses its strength with age, eventually becoming ineffective as a germicide, says the United States Department of Agriculture. An investigation has been made by the department for the purpose of determining the rate of deterioration of chlorinated lime, and the results of the study have been published in Department Bulletin 1389, entitled Deterioration of Commercially Packed Chlorinated Lime. The use of seriously deteriorated chlorinated lime for germicidal purposes, not only is a waste of money, but by affording a false security causes other precautions to be omitted and serious injury to health may result.

The investigation disclosed no marked difference in rate of deterioration between samples manufactured and packed in winter and those put up in summer. There was, however, a seasonal variation, the loss of available chlorine being greater in warm than in cold weather. This loss seems to be slightly accelerated by light.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

An International Congress on Tuberculosis.—An international tuberculosis congress is being arranged by the National Tuberculosis Association to be held in Washington, D. C., October 4-7, immediately after the meeting of the International Union Against Tuberculosis, which meets in the same city, September 30th to October 2d. Among distinguished men and women who have promised to be in attendance and who will address the various sessions are Sir Robert Philip, founder of the famous dispensary system of Edinburgh; Col. S. Lyle Cummins of Cardiff, Wales, director of the King Edward VII Research Foundation for Tuberculosis; Dr. G. B. Roatta of the Tuberculosis Dispensary of Florence, Italy; Prof. Gaetano Ronzoni, professor of medicine at the University of Milan; Dr. Vittorio Ascoli, professor of medicine at Rome; Dr. Léon Bernard of Paris, professor of hygiene and secretary of the French National Tuberculosis Association; Dr. Edouard Rist of Paris, physician to the Laennec Hospital; Dr. Ferdinand Sauerbruch of Munich, a leading authority on surgery of the chest; Prof. Frederick Neufeld of Berlin, director of the Robert Koch Laboratories; Prof. Lydia Rabinowitch of Berlin, one of the leading bacteriologists of Germany; Dr. Ernst Loewenstein of Vienna, the famous bacteriologist; and Prof. Hans Christian Jacobaeus of Stockholm, well known surgeon of the chest. Among others who are expected to attend the meetings, are Dr. A. Rollier of Leysin, Switzerland, authority on heliotherapy; Dr. F. N. Kay Menzies of London, well known authority on colonies for cured cases of tuberculosis; and Sir George Newman, Minister of Health of Great Britain. Special arrangements will be made for interpreting papers in foreign languages, and all papers will be published in the transactions.

Department Issues Flood Warning.—The Division of Sanitation of the New York State Department of Health has called the attention of water boards and waterworks officials to the possible contamination of the public water supplies under their control from flood conditions, which may arise when the present accumulation of ice and snow melts.

The contamination of water supply streams during these flood periods is more serious than at seasons of low flow. At times of flood, surface wash carries into the streams filth from animal enclosures, privy vaults and cesspools which has been accumulating for a number of months. Under the influence of rapid stream flow such contamination is carried to the water supply intake comparatively quickly and, consequently, the danger of contamination of the water supply is correspondingly greater. In the case of supplies obtained from wells or springs, contamination may occur due to the unusual hydrostatic conditions of the ground water arising from flood conditions. Waterworks officials have therefore been urged to make every effort to minimize and prevent the contamination of their supplies by careful inspection of the watersheds and, if possible, by putting premises thereon in such sanitary condition as to preclude the entrance of infected material into the streams. They have also been advised to look over and place water purification plants in perfect condition in order that they may be ready to meet the extra burden during periods of turbid and possibly infected water.

"That Priceless Ingredient"

—integrity—without which no remedial agent has any claim to a physician's confidence—has always entered in full measure into the preparation of

Gray's Glycerine Tonic Comp.

(*Formula Dr. John P. Gray*)

IN view of the implicit confidence medical men have been able to place in the therapeutic dependability of Gray's Glycerine Tonic for over a third of a century, is it strange that so many have come to look on it as one of their chief therapeutic assets?

Since its introduction to the medical profession—over thirty-five years ago—the quality, character and pharmacologic strength of this tonic restorative have been constantly and faithfully maintained.

VALENTINE'S PREPARATION
NUTRIO PER ME
VOLUME 1 4/5 OZ.
MEAT JUICE
The result of an Original Process of preparing Meat and extracting its Juice by which the elements of nutrition are obtained in a State ready for immediate absorption.
DIRECTIONS. Dissolve one teaspoonful of the Preparation in three tablespoonfuls of cold or warm water; boiling water changes the character of the preparation

Tuberculosis

Robert Alfred Bindley, M. D., *Late Resident Medical Officer North London Hospital for Consumption:* "I used considerable quantities of VALENTINE'S MEAT-JUICE when Resident Medical Officer of the North London Hospital for Consumption, and consider it of great use in feeding up those who are in a wasted condition, and who suffer severely from digestive disturbances."

Pietro Borromeo, *Physician and Surgeon of the Hospitals of Rome, Italy:* "I have tried VALENTINE'S MEAT-JUICE in the Tuberculosis Division of the Hospital of the Holy Spirit, and have proved the great advantages that it renders for the nutrition of the Consumptive. Pleasant to the most fastidious taste of the sick, it does not irritate the stomach; but stimulates the peptogastric functions so as to improve notably the appetite, even in cases of continuous and high fever and of extreme loss of strength."

For Sale by American and European Chemists and Druggists.

VALENTINE'S MEAT-JUICE COMPANY

M-402 **Richmond, Virginia, U. S. A.**

Miscellany.

The Old Steam Baths of Finland.—The affection of the Finns for the old steam bath depends partly on the general belief that it is a Finnish institution, writes Dr. Sakari Palsi (*World's Health,* February 1926). But a strong and profound love for the baths existed ages before the Finnish national spirit was kindled. "We are not the sole inventors of the steam bath; we share this honor with other nations." With the Slavs the steam bath was known of old and the present day Russian also knows the art of steam bathing and enjoys it. At the time of Jermak and his fellow Cossacks, the steam bath was known even in distant Siberia, where the steam bathers were as enthusiastic as the Finnish. The Eskimos and the native Indians in America also had hot baths, closely resembling those in Finland.

The northern nations long ago found that the steam bath helped them to keep clean in a cold climate and under primitive housing conditions. Perhaps the intense heat of their baths was a reaction to the lack of climatic warmth. The method of bathing throughout the North includes a sudden change of temperature which the bathers induce by plunging from glowing warmth into cold water or snow. This is something which southern nations look upon with awe and wonder. Curiously enough an ancient Arabian traveller expressed his feelings about the bathing of the Finno-Ougrian Mordvines in Central Russia in almost the same words as a presentday American ethnographer his fear concerning the effects of hot steam and icy water on the skin of the Eskimos. "These doubts of other peoples appear rather amusing to the Finns who have lost their fear of the heat of the bath during childhood when the mother's firm and expert hand wielded the broom of fresh birch sprays and beat the taste for the steam bath into their little bodies. The effect of the cold water is best remembered from those times when, as children, we tried to sit in the bath house with the old and experienced bathers, and with skin burning and in a state of suffocation we sought to save ourselves by rushing into the sea, already covered with the first ice of autumn. If it was early in the spring, we found the first holes in the ice and felt the cold water like an electric massage stimulate our inflamed skin. The men coming from the hot steam of the bath are able to endure the cold, and many are like those heroes of a classic Finnish novel on peasant life, who, after the bath, ran naked for long distances through the cold winter night. It is only because of lack of training that the southern nations cannot understand that, for the people from the North, effective measures are necessary for the invigoration of their stiffened bodies and for the cheer of their somewhat melancholy souls."

Although as stated the steam bath is well known to several nations of the North, in some respects the Finns are entitled to claim it as principally belonging to them. By detailed study and subtle analysis, they, more than others, have come to understand this way of bathing, and had already at a primitive stage of civilization developed its effectiveness and variety. "Evidently," writes Dr. Palsi, "the bath meets the needs of our race. We have modestly accepted it in its simple outward appearance, but at the same time have grasped its inner spiritual possibilities. Because of our renowned slowness, we find time fully to enjoy all the good which the baths offer; we are patient enough to await the effects of the different degrees of heat, we are never afraid if the red hot oven suddenly spits with rage, and with our birch tree broom we aid the even distribution of the heat. Many typical qualities of the Finnish mentality have played their part in the final perfection of the Finnish steam bath. We may say, then, that even though the steam bath is not exclusively a Finnish institution, the Finns are quite particularly a steambathing people.

"So much with regard to our outward relations to the old bath. In addition, its influence on Finnish life in general must be remembered. In developing a national bath culture, only the ancient Romans and the present day Japanese are our equals, but it seems that the Finnish have adopted their daily life even more to their bath, thus emphasizing its importance. There are thousands of individuals still alive who have gone through important crises of their lives within the bath house. Not many years ago in the country the bath house was the birth place of the home. There, too, we were nursed in our illness, and there finally we died. There no longer exist many persons whose life is so intimately connected with the steam bath. On the contrary, some people nowadays do not think the old bath an essential in the preparation for the great feasts of the year. Nevertheless, those who are born in the country have forever felt its influence. The bath house seemed to us a kind of home sanctuary, where we were expected to keep very quiet and where we learnt to worship things outside and above everyday life. The evening chime on Saturday night was always heard in the bath house, and thus our religious devotion became connected with the mysterious awe we always felt in its precincts."

The First State Pharmacy Law.—South Carolina lays claim to being the first State in the Union to have a pharmacy law. In November of 1793 the Medical Society of South Carolina petitioned the General Assembly of that State that they might be incorporated, with censorial powers of examining into the abilities of those undertaking the different branches of medicine in the State, and of inspecting the qualities of the drugs vended by apothecaries throughout the same and to condemn such as were unfit for use and to punish persons vending medicines so condemned. But it was not until December, 1817, that an act licensing apothecaries was passed. The first apothecary's license granted upon examination of an applicant's qualifications was issued to Richard Johnson, of Charleston, May 1, 1818. The first national convention of apothecaries held in the United States met in New York, 1851, through which the next year met and organized in Philadelphia the National American Pharmaceutical Association. The action of the Legislature of South Carolina, at the instance of the Medical Society of South Carolina, in statutory provision for examination and licensing of pharmacists, antedates the organization of the American Pharmaceutical Association thirty-five years, and precedes the action of the Georgia Legislature by nine years.—*Letter of John Bennett, of the Charleston Museum, to the N. Y. Times.*

DEXTROSE (Glucose), 50% SOLUTION

For Intravenous Use

Swan-Myers Company

A clear, practically colorless solution, containing 50% by weight of Dextrose U.S.P.X, prepared with double-distilled water and sterilized without the use of chemical preservatives.

The 50% Solution may be given directly into the veins if desirable, but it is usually diluted with sterile and freshly prepared distilled water or with physiological salt solution to make a 5% or 10% injection. The absence of preservative makes the solution especially desirable for oral and intrarectal use.

Packed in boxes of

6—20 cc. ampoules
25—20 cc. ampoules

The ampoules may be obtained through dealers or directly from the laboratory.

SWAN-MYERS COMPANY, Indianapolis, Ind.

Water Cress and Medicine.—Water cress has for centuries past been held delectable as a salad plant. Its scientific name, *Nasturtium officiale,* is an indication of supposed medicinal virtues, but not until recently has a chemical basis been sought for the belief of old women that its ingestion would cure bleeding cracks in the hands, and that its dietary values cause foul ulcers to heal, severe anemias to improve, and enable the body to throw off even such serious maladies as cancer. The old herbals sustain the popular belief in the value of cress as a medicine. One of them makes this statement: "We have seen patients in deep declines cured by living almost entirely on the plant. Centuries before this Xenophon expressed his knowledge of the effect of water cress on metabolism in his advice to the Persians that if they desired to improve the bodily growth of their children, they should be fed on water cress.—*Nation's Health.*

Newer Nutritional Knowledge.—Fifteen years ago we gave little concern to the kind of food we ate. We were interested chiefly in the quantity of calories which came to the table and in the methods by which they were prepared for serving. Few bakers thought of their products in terms of their food value or the rôle they played in creating healthy children or energizing the men who did the world's work.

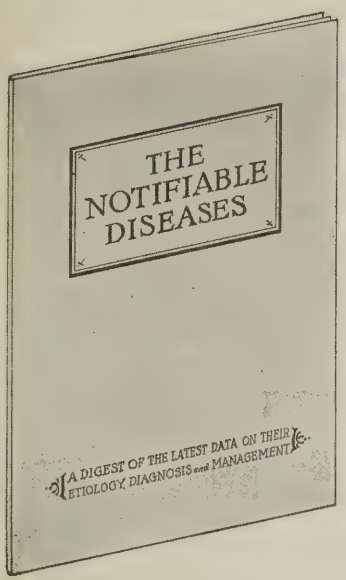
Today the situation is wholly changed. The baker has awakened to find himself recognized as a most important personage in the field of adequate nutrition. The American Institute of Baking has established a department of nutritional education which is devoted to assembling and sending out the important facts of nutrition. The biological method of studying food values has also come into prominence. The chemical laboratory almost over night was partitioned to make places for cages of small animals. Foods which until then had been tested chiefly in test tube and beaker were hereafter to be tried out on the living animal. During the last decade the life histories of many generations of rats, guineapigs, rabbits, and pigeons have yielded secrets which had been guessed but never before revealed. The changes in subject matter which this method of testing foods has introduced are no more important than the changes which have come in quieter periods of growth, but they are more dramatic in consequence. Long before 1910 there had been accumulated the great body of technical knowledge which is the foundation of nutrition subject matter today. During the present period, however, the study of protein has shifted from what was largely a quantitative study to a qualitative study, with the knowledge that proteins vary greatly in their building, repairing and maintaining values. Ten years ago mineral matter was given second place in any discussion of human nutrition needs. At the present time, it is never discussed as mineral matter, but in terms of its elements, calcium, phosphorus, iron, iodine and the others. The relationship of insufficient amounts of one or more of these elements to faulty nutrition is becoming a matter of common knowledge. The whole subject of the vitamines has been opened up, and three of these substances in foods or properties of foods have been widely discussed and definitely named. A possible fourth vitamine has recently been considered. The vitamine development represents the most spectacular occurrence in nutrition in the decade. Although the energy value of food and human energy needs had been well declared before this decade, there have been important additions to our knowledge of specific conditions affecting energy needs.

The changes both in content and method of courses in foods and nutrition in schools and colleges during the last decade have been directed toward giving students not only a knowledge of subject matter, but an enthusiasm for establishing food practices which will produce healthy human beings.—*Baking Technology.*

The Doctor's Bill.—There is nothing intimate or human about the modern physician's bill. The line "for professional services" is as cold and formal as a hospital ward and the amount may or may not be sufficient to cause the patient's relapse. By contrast the bills rendered by physicians a century or more ago had a human note in them. The physician was then more than a medical practitioner. He was the druggist and often the nurse. He administered the medicine that he prescribed. Sometimes he itemized his bill and thereby revealed the ailments to which flesh is the heir. The other day a visitor to Bermuda found a doctor's itemized bill in the library of the Historical Society of St. George's, the ancient capital of that colony. It was dated 1793 and was sent to a merchant of the town. One of the items—"to bleeding N. Daniel"—called for three shillings, fourpence. Daniel was apparently a negro slave. "Three vomits" cost six shillings and an equal amount covered three doses of rhubarb. Two shillings and eightpence was the price of a detergent, this being a cleansing medicine, and a similar charge was made for a "glass anodyne balsam," but six doses of fever powders cost six shillings. The physician was also the dentist. He charged three shillings and fourpence for extracting a tooth, and two shillings for the glass of laudanum that deadened the pain. The last item on his bill was "to visits and attendance"—one pound, four shillings.—*N. Y. Times.*

The Beginning of Syphilis in China.—In an address before the Conference on Hereditary Syphilis in Paris in October, 1925, published later in *Bruxelles Médical,* Prof. K. Dohi of Tokio presented some old Chinese books of the sixteenth century containing interesting details of the appearance of syphilis in China. The oldest of these books, entitled Shi-San-Yan, dates from 1522; it contains descriptions of five cases of syphilis with their symptoms, which are absolutely incontestable in at least three cases. This work is six years earlier than that of the Spanish physician, Diaz de Ysla, to which is attributed the earliest detailed description of syphilis in Europe. In a second book, Tsuk-i-Shut, the beginning of syphilis in China is clearly mentioned. The author, in the course of his description of a plant analogous to sarsaparilla, writes: "In the last years of the Hung-Chi period (1488-1505), there prevailed among the people a terrible eruption which spread first from Canton. The inhabitants of Wu did not yet know this malady and called it Kuang-Chuang, or Yeung-Mui-Chang." The latter is the name now for syphilis in China. It is derived from the name of a plant which presents certain analogies in color with syphilitic eruptions.—*Æsculape.*

The Notifiable Diseases



Their etiology, transmission, incubation period, diagnosis, duration, quarantine restrictions, and terminal disinfection.

Prepared under expert supervision, this timely booklet has been especially arranged to furnish the busy practitioner with a wealth of condensed information concerning the contagious diseases, that he cannot obtain elsewhere except at the cost of much time and effort.

If you would like to have a copy of this remarkably useful and attractively printed booklet, send in your request today with your professional card, and it will be sent free of all expense, by return mail.

If you wish to test **Gray's Glycerine Tonic Comp.** in some case of debility, malnutrition or convalescence after Grippe, Measles, Scarlet Fever and so on, a liberal sample is at your service.

Valentine's Meat-Juice

In **Gastric** and **Intestinal Troubles,** in **Febrile Conditions,** and before and after **Surgical Operations** when the **Stomach** is **Rejecting Food, Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** to **Restore** and **Strengthen.**

In Hospital Practice

P. McDonnell, *M. B. Hon. Surgeon, Lowestoft and North Suffolk Hospital, Lowestoft, England:* "We have found VALENTINE'S MEAT-JUICE invaluable in cases of shock and collapse of men who have been blown up in their ships by mines and torpedoes. Some of the patients have been severely injured, often for hours before admission here, and VALENTINE'S MEAT-JUICE has been the only food they could retain."

Dr. E. Duloroy, *Physician Accoucher to the International Hospital, Paris, France:* "A young accouchée, in a very weak condition and suffering from stomach trouble, could retain no food, but was able to assimilate VALENTINE'S MEAT-JUICE given at first in small doses. An improvement was quickly visible, the patient recovered her strength and is to-day in good health."

For sale by American and European Chemists and Druggists.

VALENTINE'S PREPARATION
NUTRIO PER ME
VOLUME 1 4/5 OZ.
MEAT JUICE
The result of an Original Process of preparing Meat and extracting its Juice by which the elements of nutrition are obtained in a State ready for immediate absorption.
DIRECTIONS. Dissolve one teaspoonful of the Preparation in three tablespoonfuls of cold or warm water; boiling water changes the character of the preparation

VALENTINE'S MEAT-JUICE COMPANY

Human Experiment Stations.—For fifty years and more experiment stations have developed and directed our agricultural activities. In their laboratories new fruits and grains have originated, scientific methods of fertilizing soils and cultivating crops have been worked out to increase production, and the breeding and feeding of animals have been developed so successfully that no modern farmer varies his plan of raising and maturing beef or dairy cattle, his sheep or hogs, from the methods devised by experts. There is no guess work in the rationing of well bred live stock. Every bushel of corn fed is expected to produce the maximum poundage in pork, and the ration of a dairy cow is calculated to turn high protein and carbohydrates into milk and butter fat with minimum waste in the process. All the science of chemistry has been brought to the solution of the farmers' problems. Every forward step in nutrition has been promptly applied to animal feeding.

But no such scientific control has been applied to the feeding of the human family. Facts which have been recognized as necessary to the operation of a profitable dairy have as yet never been translated into terms applicable to the children and adults of the dairyman's family. That is why more than fifty per cent. of our school children are undernourished, and why, even in the country, child life is far less well cared for than the livestock in the farmyard. This strange and illogical situation is usually explained by the statement that the result of the proper feeding of beef cattle or dairy cows is directly reflected in increased income, while the feeding of the family around the dining table is a matter of personal preference, convenience and cost. If this is true, it is high time experiment stations were established for the study of the nutrition of the higher animals known as human beings, and the methods which have been so successful in the barn brought into the home. —*Baking Technology.*

Regulations Drafted for Tetraethyl Lead Gas.—Tentative regulations governing the manufacture, distribution, and use of tetraethyl lead gas and suggestions for regulations covering the sanitation of garages have been submitted by Surgeon General Cumming, of the United States Public Health Service, to the health officers of the various States for their consideration, comment and criticism. These regulations, when finally adopted, will mark a distinct step forward in the safeguarding of the manufacture and handling of dangerous chemicals. Of far more importance to industrial workers than the control of the manufacture of tetraethyl lead is the suggestion for regulations covering the sanitation of garages. During the recent investigations of the United States Public Health Service of the possible health hazard from the use of tetraethyl lead gasoline, it was found that lead was present in the dust of ordinary garages, and in one instance it formed as much as one per cent. of the total inorganic matter. When one considers that there are hundreds of thousands of garage workers, the extent and well nigh universal distribution of this health hazard is at once apparent, and the necessity for sanitary regulation obvious.

What Is Your Idea of Mouth Hygiene?

We will pay $100 for the best short article on "Mouth Hygiene" received before July 15, 1926.

Dr. A. J. Asgis, D.D.S., Dean and Prof. Stomatology Polyclinic Hospital, says: "The toothbrush is contra-indicated in mouth hygiene."

Dr. O. T. Osborne, Prof. Emeritus, Yale, says: "Bristles may prick the gums and cause the very infected areas they are supposed to prevent."

Dr. J. Kelly, D.M.D. (L.I.M.J. 1920), says he is "bitterly opposed to the toothbrush. For it injures the gums by cutting them and is a source of serious infection at times."

Dr. N. Whittaker, Form. Div. Child Hygiene N. Y. C., says: "The toothbrush in use is a septic instrument and any physician or intelligent dentist recommending it, is just as guilty of malpractice as though he used a septic instrument himself."

An Editorial in the N. Y. Med. J., 1919, on the subject of the toothbrush, says it injures the gums and rubs into the injuries "whatever bacteria it may have gathered anywhere throughout the mouth."

L. L. Baker, D.D.S. (The American Dental Surgeon, Apr., 1926), condemns the toothbrush as being unsanitary, and asks: "Can you keep your mouth clean by using one?"

The toothbrush is a breeder of bacteria, a retainer of food particles until they decay, a collector of bathroom dust and odors.

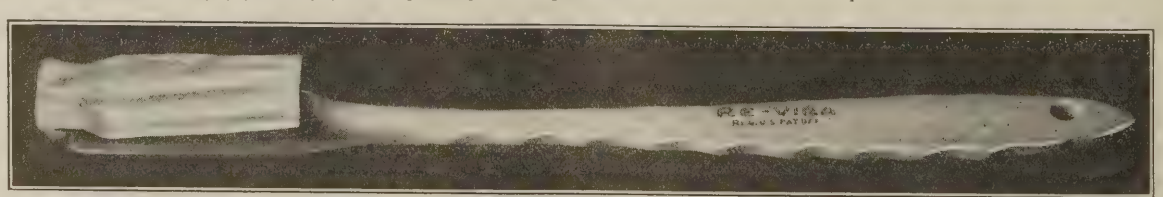
We have offered $1,000 to anyone who can prove the use of the toothbrush is not UNSCIENTIFIC, UNHYGIENIC AND DANGEROUS.

People have been misled into thinking the toothbrush cleans inter-proximal spaces CLEAN.

There are several substitutes for the toothbrush. Paper (used by a well known health institute), cotton and cloths.

RE VIRA

provides a convenient means of using a new cotton pad with each cleaning of the teeth. Use pad first slightly wet, then thoroughly wet. Outfits, adult size, $1; childs, $0.75. Special price to physicians and dentists. No samples.



THE RE VIRA COMPANY Ridgefield Park, N. J.

DIABETES, TOXEMIA AND DIABESAN

Dr. C. A. M. of Atlantic City, New Jersey, writes us under date of January 20th, 1926, as follows:

"Gentlemen:

Kindly send me one thousand (1000) tablets of Diabesan. I am using your Diabesan in many cases of intestinal toxemia and diabetes with surprising good results.

Enclosed please find check.

With my best regards,

Yours,

(Signed) C. A. M., M.D."

Diabesan is efficacious and harmless. There is no danger of an overdose.

The Hand of Mr. F. T. Paul.—At the conclusion of the clinical meeting of the Liverpool Medical Institution on March 11, 1926, Mr. J. C. M. Given presiding, the members assembled in the lecture theatre to witness an interesting little ceremony—namely, the presentation to the institution of a bronze cast of the right hand of Mr. F. T. Paul, executed from a cast by Mr. H. Tyson Smith. Mr. Frank Jeans, the donor of the bronze, said that Mr. Paul's name was known to every surgeon as a pioneer and an inventor, Paul's tube being as epoch making an instrument as that of another Liverpool surgeon, Thomas's splint. Therefore he thought that, as a remembrance of Paul, a past president of the Liverpool Medical Institution and a most gifted operator, a cast of his hand would be acceptable to the institution. "Paul's operating in the heyday of his manual efficiency," he said, "always made me think that he did with his hands what Pavlova did with her feet, only Paul's work was much more useful. I have an additional reason for wishing to pay a tribute to Paul, because it is to him that I owe the continued existence upon this earth of my wife—but that is a personal matter." Mr. Paul, in acknowledging the courtesy of the institution in accepting the gift and the kindness of Mr. Jeans in thinking of it, admitted that at first he had regarded the matter somewhat as a joke, and, while confessing that he had always been fond of using his hands from his earliest years, he reminded the audience that "a gentle touch comes from the heart rather than from the hands, a touch inspired by a true sympathy with the patient's tissue—in this way only could a man attain the hand of a surgeon." The president then expressed his pleasure in accepting the bronze cast in the name of the Liverpool Medical Institution, and thanked Mr. Jeans most sincerely for his very acceptable gift. All our readers will acknowledge the fitness of the retention in the Liverpool Medical Institution of a permanent memorial of the work of Mr. Paul. Not only is he a great as well as a skilful surgeon, but he was one of the founders of the Liverpool Medical School, and from its earliest days his work has contributed to the building up of the great tradition of that school.—*The Lancet,* March 27, 1926.

Chinese Vertical Writing Found Easiest Reading. — Chinese, oldest of languages, is commonly thought of as the most difficult. But this is an error, if the difficulty of a langauge is measured by the speed with which it may be read. Prof. Walter R. Miles, of the department of experimental psychology of Leland Stanford University, and Eugene Shan, a graduate student, in a series of comprehensive tests have learned that Chinese may be read more rapidly than English, and that type set vertically is more efficient and causes less eye strain than type set as is this. In arriving at these conclusions Dr. Miles made use of eleven Chinese students, all of whom were born in China and were brought up on "vertical newspapers"; that is, on Chinese print reading up and down. He photographed their eyes, measuring their movements and noting how long each rested on a single group of words and calculating from that their speed in reading the two classes of selections. While the entire eye was illuminated and photographed it was the cornea, or white of the eye, that presented the opportunity for study. The cornea, being illuminated, changed its angle of reflection during each movement. The scientists found that the eye is never absolutely still, for when photographing a member fixed on a single spot, its edges left a hazy outline on the negative.

The selections read were in both English and Chinese, taken from a magazine article. The Chinese was set both horizontally and vertically for various experiments. It was found that at each reading pause the eye perceived a greater number of words of vertical type than of horizontal, while a greater number of vertical words were read each second than were horizontal words. The vertical reading matter, which Dr. Miles found to be more efficient, if applied to newspaper and magazine columns in the United States would bring about this change: You would commence reading at the upper right hand corner of the column or page and read down, progressing by columns from right to left. Each succeeding letter of a word would be set beneath its predecessor rather than alongside. Punctuation marks to indicate pauses, sentences and paragraphs would be used as at present. It has been a popular idea of long standing that horizontal reading matter may be perceived and understood with less strain to the eye, and, in fact, many Chinese papers have changed over to this style of type setting during the last few years. But Dr. Miles's analysis of his investigations indicate this to be an erroneous impression. Investigations subsequent to those he has already reported upon bear out the earlier conclusions. —*Science Service.*

Child Welfare Work in France.—Child welfare courses have been organized by various charitable institutions for women and girls of the leisured classes at the *Fondation Budin,* the dispensaries of *la Glacière* and the *Rue de la Convention, Les Annales,* and the Red Cross Central School of Child Welfare. Lectures are given at the Lariboisière and Charité to women teachers following the health courses at the Institute of Home Medicine. After the war certain journals devoted a column to child welfare, or published authoritative papers on the subject. In 1922 at the International Congress for the Protection of Motherhood and Childhood held in Paris, it was unanimously voted that "the problem will be facilitated to a great extent when a simple course of lectures, adapted to the ages of the pupils, on child welfare and hygiene is included in the curriculum of schools for girls and young women, with permission for the subject to form part of their examinations." In 1923, the Minister of Health, Paul Strauss, and the Minister of Education, Léon Bérard, issued a decree by which the teaching of child welfare became compulsory for girls in the higher classes of the primary schools, and included besides theoretical instruction given by the women teachers, visits to day nurseries and baby welfare clinics. A clear and condensed series of ten lessons, prepared and published by the National Committee on Child Welfare, and a little book on mothercraft were used as a basis of instruction. "Finally," writes the author, "to supplement and complete the program for the popular teaching of child welfare, I compiled, at the request of the Minister of Agriculture, an elementary course in seven lessons entitled Mothers of the Future, which has been adapted for the cinematograph."—*World's Health.*

Long Distance Running Unnatural.—A study of the muscular activities of primitive man teaches the lesson that neither anatomically nor instinctively is man, civilized or uncivilized, equipped for long distance running. In the primitive state he does not resort to it as a means of protection from wild beasts, which, by the way, are little likely to atack him unless molested. Nor in his hunting expeditions is he called upon to run long distances, for his method of hunting is essentially that adopted by most carnivora, i. e., by stalking. In short, under natural conditions man rarely, if ever, has occasion to run long distances. When trekking in search of fresh pastures he walks. Short distance running serves most if not all his purposes, as in play, and in seeking shelter.

It would thus appear that long distance running is not natural to man, and, such being the case, it is difficult to see what good purpose can be served by it, as regards either health or physique. It is evident that it must put considerable strain on the heart, seeing that the vigorous rhythmic contractions of practically all the voluntary muscles of the body drive the blood into the right cardiac chambers in quantities many times greater than during rest or moderate exercise, and unless the right ventricle is able to deliver its contents into the lungs with sufficient promptitude, dilatation of that chamber is apt to ensue. On the other hand, in games involving intermittent strenuous exercise, such as tennis, the heart is afforded ample opportunity to recover itself after each bout, and this game can be played with impunity for hours together by many people past middle life, provided the heart muscle is healthy and well supplied with blood, and provided also the arterial blood pressure is low. —*Medical Press and Circular,* March 10, 1926.

Newspapers Help to Protect Unfortunate Children.—One of the latest contributions of the newspapers to the education of the public in matters relating to child welfare is in connection with advertisements of boarding homes for children. In response to a request from the State Commissioner of Health for cooperation in the enforcement of the law requiring any person who conducts a boarding home for children to have a license from the local board of health, many of the newspapers are refusing to accept advertisements unless evidence of the compliance with the legal requirements is furnished.

The following notice published daily by the *Knickerbocker Press* of Albany, on one of its advertising pages, illustrates a method which is very effective:

Board for Children

Any person who conducts a boarding home for children, a maternity home or a day nursery is required by LAW to secure a license from the local board of health granting them this authority. No advertisement will be accepted under this classification unless presented personally by the advertiser with written permission to advertise signed by the health officer.

The department finds that such a statement published daily accomplishes three things, viz., it acquaints the advertiser with the law, it put persons seeking such homes on guard against places holding no license, and it furnishes the department with a check on persons boarding children, thereby enabling it to investigate and find out if they are meeting other requirements of the law in the conduct of boarding homes and day nurseries.—*Health News.*

Quinine Shortage.—That there is a definite shortage of quinine and that this is in great measure due to the Dutch monopoly is proved beyond doubt by the report of the experts who were appointed as a special subcommittee by the Malaria Commission of the League of Nations, says the *Medical Press and Circular.* According to their findings, there is a distinct shortage of quinine available for sufferers in many districts; the high prices render its liberal use impossible; and the method promising best results would be the discovery of the efficacy of some combination of the alkaloids of cinchona, other than quinine, which could be obtained from the trees grown in countries other than the Dutch East Indies. The world's annual production of cinchona bark is about ten thousand and six hundred tons, of which about nine tenths is produced in the Dutch East Indies; of the remainder India produces eight hundred and seventy tons, South America two hundred tons, and Africa fifty tons. The percentage of quinine from Dutch bark is from six to seven per cent.; from Indian bark, from four and five tenths to five per cent.; from Peruvian and other barks, from two and five tenths to four and five tenths per cent. Existing factories produce only six hundred thousand kilograms annually, a supply considerably below the demand: one factory alone in Java produces one third of the total world's supply. Amsterdam fixes the market price by a convention entered into between the growers and manufacturers; and the present price yields a return of about thirty-six per cent. on invested capital. The production is strictly limited, and the amount of quinine in the open market is negligible.

Hibernation.—The study of hibernation in animals has been a favorite pursuit of many scientific men. One of John Hunter's papers to the Royal Society embodied an account of various experiments he had made some years before upon the heat of animals and vegetables, proving that living bodies possess a power of maintaining their heat against the influence of external cold in a degree proportioned to their rank in the scale of organization.

The hibernating state of animals has nothing analogous in the life of man. In some it is continuous through the winter until the spring; in others, while interrupted by sunny days, it begins again with the return of cold weather. The bat, the marmot, and the dormouse belong to the former class; the bear, the badger, the polecat, and the hedgehog to the latter. The condition of hibernation is characterized by unconsciousness, lowered body temperature, retarded circulation, slight superficial breathing, no ingestion of food, no elimination of excreta, a condition of minimal passive metabolism. The energy required is secured from the oxidation of fat, and the mammals have a special gland which serves this purpose in hibernation. Some species of fish, as pointed out by Cuvier, possess the opposite faculty of summer sleep and, burying themselves in the mud when the water around is dried up by drought, become torpid until the advent of moisture awakens them. During the dry season, lizards, crocodiles, snakes and toads lie in the ooze of swamps and river beds until the rain comes.—*Medical Press and Circular,* March 17, 1926.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

Pollen Sensitization.—J. H. Black, in the preliminary report published in the *Journal of Laboratory and Clinical Medicine,* February, 1925, concludes from his investigation on the standardization of pollen extracts that the active substance in pollen is not a protein, nor does the work support the suggestion of Grove and Coca that it is related to an enzyme. None of the methods of standardization of pollen extracts in common use were found to be of value. The reaction of the nasal mucosa of a ragweed sensitive individual may serve as a reliable criterion for the determination of the amount of active substance in ragweed pollen extracts.

Pamphlet Instruction Reduces Venereal Disease Cases.—The practical value of giving young men information regarding the venereal diseases is attested by word received by the United States Public Health Service from one of the recruiting agencies of the United States Shipping Board. Some time ago, the Public Health Service supplied the Recruiting Service of the Shipping Board with pamphlets suitable for distribution to young men. These were given out to the men of the crews on vessels operating to the Orient and the results have been designated as farreaching. Physicians attached to passenger vessels report that the distribution of these pamphlets among the crews had the effect of very considerably reducing the number of venereal disease cases.

Results Obtained With New Tuberculosis Vaccine.—Professor Calmette, of the Pasteur Institute, Paris, read a paper recently before the Paris Academy of Sciences in which he described the results he has obtained with his new vaccine against tuberculosis, administered in newly born babies. Not one of the children subjected to the original experiments in 1921 and 1922 succumbed to any disease of tuberculous origin. In 1924 and 1925 another group of babies numbering 5,183 were vaccinated, of whom only seven tenths per cent. died from diseases presumed to be of tubercular origin. According to figures published by the Public Health Bureau, from twenty-five to 32.3 per cent. of children born in surroundings infected with tuberculosis ordinarily die. The vaccine appears to retain its efficiency from fifteen to eighteen months.

A Nationwide Appeal for Better Obstetrics.—A joint committee representing the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, and the American Gynecological Society, has organized a nationwide propaganda to present an appeal for better obstetrics, more definite prenatal care, and rigid asepsis. Through state chairmen of groups of lecturers, concerted effort will be made to have a maternal welfare program given before every county and district medical society in each state. Names of speakers will be furnished by the state chairman to the secretary of the state society, from whom secretaries of district and county societies may obtain information. The organization of the committee is now comprehensive throughout the United States, and is beginning to function in a very effective manner.—*Bulletin of the American Medical Association.*

Miscellany.

Twentieth Century Progress in Preventive Medicine.—Keeping well has always been a profound concern of humanity, but the idea that diseases can be prevented by the intelligent application of human knowledge is of recent birth. Indeed this conception of the problem is still so young that developments growing out of it have taken place largely within the memory of those yet alive.

As a manifestation of these developments, witness the phenomenal growth of public health organizations.

In 1909 most of the extragovernmental health associations and societies were either not in existence or scarcely more than nominal institutions so far as membership and resources were concerned. Today there are more than a score of powerful national agencies, most of which are coordinated in the National Health Council, and innumerable local organizations with combined resources that would do credit to a national budget. Every state and every city worthy of that name maintains a health department; innumerable welfare, civic, social and fraternal clubs and societies have sections and departments of health. Wealthy men have created scores of foundations with almost unlimited resources for promoting public health service. Insurance companies have undertaken extensive crusades against disease and are maintaining highly developed laboratories and large field staffs for carrying on this sort of work.

So important has health organization become that the League of Nations has created and maintains a highly developed health section. In the United States there has been and still is a strong sentiment in favor of creating a national health department, headed by a cabinet member. Another large movement in this country is the Pan-American Sanitary Bureau, including in its membership the nations of North and South America.

A big commercial concern with very extensive holdings in the American tropics recently initiated and paid the bills of an international conference on health problems in Tropical America, which was held at Kingston, Jamaica, and brought together eighty-eight of the world's outstanding authorities on public health and sanitary problems. Such an undertaking would have been considered almost ridiculous twenty-five years ago.

The first county health department was organized as late as 1911. Now there are something like 270 of these important public health administrative units scattered throughout the United States.

At the beginning of the century there were very few publications devoted chiefly to preventive medicine, and probably none of a popular character. Now the market is flooded with health literature, some of which is of course questionable. Practically all the state health departments publish and distribute gratuitously pamphlets relating to communicable diseases. Not a few of these departments as well as the city health departments generally publish weekly or monthly bulletins on timely health subjects, vital statistics, etc. A number of insurance companies have gone deeply into health propaganda, and various

INTERESTING INVESTIGATIONS MADE AT THE HORACE GREELEY LABORATORY

April and May 1926, and by Dr. L. H. Cornwall, Bacteriologist New York City

36 new toothbrushes were purchased, placed in separate test tubes and sterilized.
Brushes were given to as many people. After cleaning the teeth each brush was rinsed in water and returned to its container.
Into each container was poured 10 cc of sterile 0.9 per cent saline (covering bristle end of brushes) and the containers returned to the ice-box for 24 hrs.
Brushes were then shaken out in the saline and removed from the tubes. Tubes were then well shaken and .01 of a cc of the contents of each was planted on a tube of Loeffler's blood serum and the latter incubated for 24 hours.
The saline remaining in the 36 tubes was then transferred to as many centrifuge tubes and centrifuged for five minutes at 2200 revolutions. Smears were made of the sediment and stained with methylene blue. Identification of organisms was made from their morphology in the above mentioned smears and in smears from cultures and replants, and peculiarities of growth in replants upon various media. Altogether some 500 cultures and 600 smears were made and examined.

FINDINGS IN CONDENSED FORM

36 (all) of the brushes showed Staphylococci, aureus or albus or both,
31 of the same brushes showed Pneumococci,
19 showed streptococci, non-hemolytic,
1 showed streptococci hemolytic,
11 showed Vincents angina.

10 brushes used only five days were examined by Dr. Cornwall for organic matter. It was demonstrated in every case.
12 brushes of diphtheria cases were examined. 9 showed diphtheria bacilli. One week later 8 of the brushes still showed diphtheria bacilli.

As a result of these findings how can we reconcile ourselves to the use of the toothbrush for practicing MOUTH HYGIENE.

RE VIRA

Provides a clean pad each time the teeth are cleaned and the gums massaged. Outfits, Adult's $1. Child's $0.75. Special price to Physicians and Dentists.

DIABETES, TOXEMIA AND DIABESAN

Dr. C. A. M. of Atlantic City, New Jersey, writes us under date of January 20th, 1926, as follows:

"Gentlemen:

Kindly send me one thousand (1000) tablets of Diabesan. I am using your Diabesan in many cases of intestinal toxemia and diabetes with surprising good results.

Enclosed please find check.

With my best regards,

Yours,
(Signed) C. A. M., M.D."

Diabesan is efficacious and harmless. There is no danger of an overdose.

medical associations publish popular health literature. Household magazines, newspapers, the radio and the movies have all joined in the good work.

Industrial hygiene has come into being as a definite part of the practice of preventive medicine during the present century. In 1900 only eleven states were included in the United States Registration area for deaths. Now all but eight states in the Union are in federal registration area. Mental hygiene has developed only within the last decade, and promises to become a predominating factor not only in revolutionizing the methods of handling criminals, but in allocating individuals into suitable school classes and vocations, thereby increasing at once efficiency and happiness.—*Abstracted from Illinois Health News.*

Milk a Century Ago.—Before a recent meeting of the Brooklyn Pediatric Society, Dr. Harris Moak, in discussing the sanitary control of clean milk, read the following paragraphs from Louden's *Encyclopedia of Agriculture,* which has a preface bearing the date June 20, 1825, just a century ago. The quotation is most apt just now when New York City is so greatly interested in the milk problem:

"The milk used by the human species is obtained from various animals, but chiefly from the cow, ass, ewe, goat, mare, and camel; that in most general use in British dairying is the milk of the cow, which in modern times has received great improvement in quantity as well as quality, by ameliorations in the form of milch cows, in their mode of nourishment, and in the management of the dairy.

"The constituent parts of milk are found to be oil, curd, gelatine, sugar of milk, muriate of soda, muriate of potash, phosphate of lime and sulphur. These substances enter into the milk of all animals, but the proportions varying in different species.

"The properties requisite in a good milkhouse are, that it be kept cool in summer and moderately warm in winter, so as to preserve a temperature nearly the same throughout the whole year, or about 45°; and that it be dry, so as to admit of being kept clean and sweet at all times. For these reasons a northern exposure is the best, and this as much under the shade of trees or buildings as possible; if it can be so situated that the sun can have no influence either on the roof or walls, so much the better. A well constructed butter dairy should consist of three apartments: a milkhouse, a churning house, with proper boiler, as well as other conveniences for scalding and washing the implements, and a room for keeping them in, and for drying and airing them, when the weather will not permit of its being done without doors.

"To promote cleanliness in regard to milking, cows are in some places curried, combed, brushed, and clothed like horses; before milking their udders and teats were washed and dried, and their tails trussed up. It would be well if a part of this refinement were adopted in all dairies; that of using the comb and brush, and washing the udder, is indispensable in every establishment where clean milk is an object. According to Moubray snuff takers, sluts, and daudles are unfit to be dairywomen, and no milker should ever be suffered to enter the dairy in a dirty apron covered with hairs from the cowhouse."—*Long Island Medical Journal.*

Cancer in Relation to Occupation.—An investigation into the statistics of cancer in different trades and professions by Dr. Matthew Young and Mr. W. T. Russell, with the collaboration of Dr. John Brownlee and Dr. E. L. Collis, was recently published by the Medical Research Council. The work was made possible by the courtesy of the Registrar-General in affording facilities of access to certain documents in his possession. These included cards on which were coded the sex, age, specific trade, and cause of death of men who died in 1910, 1911, and 1912. On 46,118 cards which recorded deaths from malignant disease the site of the tumor was for the most part noted, and it has thus been possible to make a detailed survey of the relation of cancer to occupation.

A brief introduction is followed by a discussion of previously published data. The methods of analysis used in this investigation are then set out. There follow sections on the incidence of cancer in the principal sites in different occupations, and on the relationship between different types of cancer, between cancer in different sites and syphilis, and between cancer and chronic alcoholism. The conclusions of the investigation are then briefly summarized. The close association of some types of cancer with exposure to particular risks—for example, chimney-sweeps' cancer and mulespinners' cancer—has been confirmed, but no conclusive evidence has been obtained of such a connection between the nature of the employment and other forms of cancer, notably internal forms. In some occupations excessive smoking and drinking, which is permitted or facilitated by the nature of the occupation, appears to be the important predisposing factor and not anything inherent in the employment itself, while the incidence of syphilis in different occupational groups seems to have some association with that of lingual cancer. With the main conclusion that occupational risk is only one of several predisposing causes of cancer in different instances and under different circumstances all are likely to agree.

It was hoped that such an examination might give further information as to the wide influence of substances already recognized as harmful, or might even disclose other injurious substances. But the difficulty of interpreting the material has proved very great, and the result of a praiseworthy and laborious effort appears on the whole to be disappointing. In many trades or occupations the number employed is small and consequently the number of deaths is liable to considerable random error. Again, statistical science is still in a developmental stage, and there exists difference of opinion between persons equally competent to judge as to the applicability of particular methods of comparing figures. For example, the strong preference expressed by the authors for the use of the socalled life table death rates over standardized death rates is not shared by some of their colleagues, and there are other technical points over which experts are not yet in agreement. The use of the method of proportional mortality has the disadvantage that the proportion of cancer of any particular site in one occupational group may be high simply because within that group the rate of mortality from cancer of another site is low, and the majority of the Statistical Committee of the Council are of opinion that conclusions based upon this method and unconfirmed or incapable of confirmation by a study of the site rates themselves should be accepted with reserve. However, sufficient material is provided in the tabular matter of this report, and in data previously published, to permit other investigators to try and elucidate this complex subject by pursuing research on different lines.—*Lancet,* February 6, 1926.

Convalescence.—John Bryant in an interesting article, published in the *Boston Medical and Surgical Journal* for September 17, 1925, says that the convalescent patient, be he medical or surgical, has suffered and is suffering from clinical neglect, and will continue to suffer from clinical neglect until it becomes accepted routine that he shall receive adequate treatment in wards (preferably in country convalescent institutions), from which the acutely ill are excluded. Adequate treatment of the convalescent patient implies treatment by a staff especially trained in the intelligent application of such methods as were developed in the army under the supervision of the Division of Physical Reconstruction, Surgeon General's Office; a staff, furthermore, trained to care primarily not for the acutely ill, but for those patients who are convalescing or suffering from illness not of acute type. The care of convalescence reached a higher level of efficiency in the United States Army during the late war than it has ever reached before or since, in an army or in civil life.

The procedures which in our Army produced such a satisfactory degree of efficiency in the care of convalescence are available for use in civil life. Foremost among these procedures may be mentioned occupational therapy and physiotherapy. An impressive Army experience in occupational therapy has demonstrated that, in the order named, ward academic and ward handicraft work are the two sections of occupational therapy which offer greatest promise of potential or lasting value to the convalescent patient.

The civil hospital which does not adapt for its own use those Army procedures which were proven so productive of positive and beneficial results in the care of convalescence, is not yielding maximum returns to its supporters, to its patients, or to its community. Voluntary adequate community care of our armies of young convalescents is relatively inexpensive. It is the only known alternative to expensive and involuntary care of our armies of old incurables. Inadequate care of convalescents spells half completed medical work, half cured patients, financial inefficiency, and economic waste.

Factors Influencing Recovery in Accidents.—E. McD. Stanton (*International Journal of Medicine and Surgery,* June, 1925) points out the importance of certain psychic factors in the recovery time of ordinary accidents. The physician himself may be responsible, by suggestion, for the development or avoidance of a traumatic neurosis in an accident or liability patient. Thus some physicians handling large numbers of traumatic cases seem almost never to have these neurotic symptoms develop; others regularly have them. Since return of function after a sprain or strain is a product of repair processes internally active in the individual himself, the morale of the patient becomes a very real force in effecting a normal recovery.

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

1926 Health Legislation.—From the viewpoint of the New York State Department of Health and of all who have had an interest in legislation affecting public health in New York State, the year 1926 has been a most satisfactory one, says *Health News*, May 17, 1926. The legislature has passed nine bills in which the State Department of Health was directly interested.

Chapter 185 added to the Public Health Law a new section, 25-a, providing for the control of dogs when rabies prevails, and repealed section 90 of the Farms and Markets Law. The measure was endorsed by the Commissioner of Farms and Markets.

Chapter 277 appropriated $59,387.98 to cover grants of State aid to counties.

Chapter 308 amends the Public Health Law increasing the compensation of local health officers, legalizing the appointment of acting health officers to serve in the temporary absence from duty of regularly appointed health officers, and authorizing boards of health to provide additional compensation to health officers for taking release cultures in diphtheria. The bill, identical with that introduced last year at the request of the department, was introduced this year at the request of the State Sanitary Officers' Association.

Chapter 309 authorizes the State Department of Health to make rules and regulations for the protection of the water supplies of State institutions and United States reservations. The measure was endorsed by the president of the State Hospital Commission.

Chapter 319 made an appropriation for construction of new buildings at the State laboratory.

Chapter 367 amends section 19-b of the Public Health Law relating to State aid to counties, making it more explicit and workable.

Chapter 499 amends the Public Health Law to provide that a county health unit may be abolished by the board of supervisors after two years, after a public hearing.

Chapter 635 amends the Domestic Relations Law to expedite the reporting of marriages.

Chapter 723 provides for the sale of the old Yates St. laboratory property, the proceeds to be applied to purchase of land adjoining the present State laboratory property.

One of the most notable features of the legislative session was the passage of the medical practice bill designed to facilitate action against illegal practitioners of medicine.

Rabies Prevention Bill Now a Law.—The Lattin bill relating to the prevention of rabies and adding to the public health law a new section 25-a having passed and been signed by the Governor is now chapter 185 of the laws of 1926. The act repeals section 90 of the farms and markets law under which dog quarantines have heretofore been established by the department of farms and markets.

This act further provides that when the state commissioner of health shall certify to a health officer that rabies exists among dogs in his municipality or district it shall be the duty of the health officer to give public notice and thereafter, until the state commissioner of health shall certify that rabies no longer exists, it shall be unlawful to permit a dog to be at large unless properly muzzled. It makes it the duty of all officers empowered to enforce state laws or local ordinances to cause any dog found at large and not so muzzled to be confined, or, if this is impracticable, to be immediately killed, and provides that any person killing a dog not so muzzled which is known to have attacked any person or domestic animal shall not be held liable for damages for such killing. The person killing or causing a dog to be killed under these conditions is required to report the facts to the local health officer.—*New York Medical Week*, May 15, 1926.

Valentine's Meat-Juice

In **Typhoid Fever Valentine's Meat-Juice** demonstrates its **Ease** of **Assimilation** and **Power** of **Restoring** and **Strengthening.**

I. Burney Yeo, M. D., *Professor of Therapeutics, King's College, London, in the well known work, "Food in Health and Disease":* "In a very severe case of Typhoid, under our care in King's College Hospital, with most alarming and profuse hemorrhage, we carried out a rigorous method of feeding with remarkably satisfacory results. The clear indication was to keep the intestines absolutely at rest and to allow no debris of food to pass through to excite peristaltic action. It was necessary therefore to give food which, while adequate to sustain and strengthen the patient, should be wholly absorbed in the stomach and upper part of the small intestines. To give milk might be fatal. For our purpose we selected VALENTINE'S MEAT-JUICE, giving one teasponful in a wineglassful of cold water every three hours, with one teaspoonful of brandy. The patient's diet was absolutely limited to these quantities for seven days. The plan answered admirably and the patient made a perfect recovery and fairly rapid convalescence."

For Sale by American and European Chemists and Druggists.

Miscellany.

Vacancies in the Medical Faculty of Vienna.—The Vienna correspondent of the *Lancet* says a serious situation in the University of Vienna has been caused by the unexpected death of several professors within a short time of one another. A few weeks ago Prof. Friedrich Dimmer, the well known ophthalmic surgeon, died at the age of seventy years, and his eye clinic, of which he had been the director for many years, will perhaps be dissolved. Such at any rate was the intention of the Ministry of Finance which has to find the funds for the institution, and naturally it has caused widespread consternation in medical circles. It has been justly pointed out in numerous articles and resolutions that the ever-increasing importance of ophthalmology, and of Vienna ophthalmology especially—we may recall the names of Fuchs, Fäges, and Arlt—did not allow of a purely bureaucratic measure of this kind, which would drive away many students and doctors from this country, and thus result in the loss of more money than could be saved in abolishing the expenses of the clinic. It is to be hoped that the idea will be definitely abandoned. The University staff has suffered another serious loss by the sudden death of Prof. Josef Kyrle at the age of forty-six years. He had already done important work in dermatology, his principal investigations being concerned with the treatment of syphilis by malaria, the histology of skin diseases, and the eunuchoid conditions. He was destined to succeed Prof. Gustav Riehl, who is now finishing his honorary year and has passed his seventieth year, when he has to retire according to the rules of the University. Kyrle was a brilliant teacher whose clarity and impressive diction were reminiscent of the famous teachers of forty years ago when Vienna was the Mecca of medicine.

A Health Survey of Mexico.—One of the most thorough and interesting health surveys ever made of the Mexican Republic will be undertaken this summer by Dr. Frederick L. Hoffman, consulting statistician of the Prudential Insurance Company of America. He intends to cover the larger part of the Mexican Republic in an effort to determine the existing health situation and the methods which are being employed to eradicate disease and to improve the disease resistance of the native population.

This investigation has the wholehearted support of the Mexican Government and the endorsement of many of the leading members of the medical profession and public health authorities throughout the Republic, said Dr. Hoffman. He explained that the chief objects of the investigation concern the different elements of the Mexican population, but particularly the native Indian tribes out of touch with the large centres of population. The investigation, however, he continued, will include observations on variations in temperature, altitude, humidity and other climatic factors of importance. He intends to visit most of the hospitals throughout Mexico and collect data on the physical anthropology of native Indian tribes. In addition, he intends to give particular attention to the operations of Mexican insurance laws and to the extent to which the life insurance business in Mexico has been developed by domestic or foreign companies. In the tropical section he expects to give consideration to tropical diseases, including malaria and typhus fever.

Dr. Hoffman said he hoped that the results of his investigations might prove of considerable practical value to both the Mexican and the American people and set at rest many controversial medical questions which affect seriously the future development of the Mexican Republic.

Massachusetts Institute of Technology to Give Summer Courses in Public Health.—Among the 1926 summer courses to be given at the Massachusetts Institute of Technology July 6th-27th inclusive, are the following:

Health Education Methods, designed for teachers and for school nurses who have teaching responsibilities. New methods of health teaching as they have been developed in experimental work by the instructor and by other health workers in various parts of the country will be described. In addition to the classroom work, fifteen hours will be used in observation and field work under supervision.

Health Records and Statistical Procedure, a course which deals particularly with record keeping, together with the organization and presentation of health statistics in the work of school departments, private agencies and health departments. It is expected that students will be persons in charge of public health record keeping.

Public Health Laboratory Methods, a practical course in diagnostic methods and other procedures employed in public health laboratories. Training is given in laboratory diagnosis of diphtheria, tuberculosis, typhoid fever, malaria, and certain other communicable diseases and in the Wassermann and other complement fixation tests. This course is designed particularly for physicians, laboratory technicians and those preparing for administrative positions in public health.

Further information may be had by addressing the Massachusetts Institute of Technology, Cambridge, Mass.

Less Typhoid Fever During 1925.—Of the various outbreaks of typhoid fever which occurred in the State during 1925, seven were found to be due to infected milk and two to polluted water supplies.

Thirty typhoid carriers, exclusive of those found in State hospitals, were discovered during the year to which 122 primary and 7 secondary cases of the disease were attributed. At the end of the year 125 carriers remained on the list exclusive of those in State hospitals.

There were a total of 1,483 upstate cases of typhoid fever reported in the State in 1925 as compared with 1,602 in 1924. With one exception the case rate, 28 per 100,000 population, was the lowest on record. The mortality was slightly higher than during the previous three years, but lower than other years on record.

The increased mortality was due to an excess of deaths in January which resulted from cases appearing in December 1924, in connection with the oysterborne outbreak in New York City and vicinity. —*Health News.*

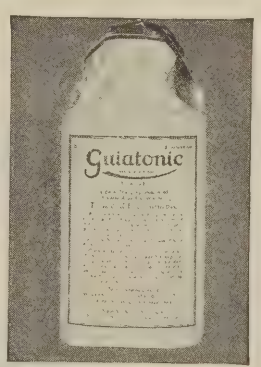
Imperfect or Incomplete Convalescence

as authoritative investigations have recently shown, is responsible for a large part of human illness.

After the fury of an acute infection subsides, the most effective measures are essential, therefore, to make recovery complete and certain. In the use of Guiatonic the practitioner has at his command a most efficient means of aiding and reinforcing the recuperative forces of the body. As a result of its regular use, the patient soon shows a substantial gain in weight, strength and vitality, with an early restoration of that state of physiologic balance that constitutes true recovery.



A palatable preparation of guaiacol and creosote which may be freely given to the weakest patient, without fear of gastric disturbance. *It contains no narcotics.*

Indicated in all depressed or debilitated conditions, or whenever a tonic is required.

Guiatonic

A liberal supply for testing free to physicians. William R. Warner & Company, Inc., Manufacturing Pharmaceutists since 1856. 113-123 West 18th Street, New York City.

Licensing of Foreign Physicians.—Heretofore physicians from abroad have always been welcomed by licensing boards in this country, and in most states the requirements, if different at all, were less strict than for graduates of our own American schools. In this connection, physicians coming from Canada have hardly been considered as foreigners. Their qualifications are as clearly recognized as those coming from medical schools of the United States. This is because Canadian physicians have had their part in the movement instigated by the medical profession of this country to improve the standards of medical education and licensure. Many of the physicians who came from abroad, also, have long since become honored members of the communities in which they reside and are mostly active members of our medical organizations. Even at this time, therefore, there is no desire to establish unreasonable restrictions against foreign physicians, especially those who are bona fide graduates of well recognized medical schools and who come from countries whose laws, customs and manners of living are similar to those of the United States.

Since the World War, however, a necessity for reasonable restrictions has developed. The numbers of physicians seeking licensure in this country have been increasing, as a result largely of the financial stress in their own countries from which they are endeavoring to escape. Among these there has been an unusual proportion whose credentials were of doubtful validity or distinctly fraudulent. It has become necessary for state authorities to establish legal safeguards over the admission of physicians from abroad. The requirement of American citizenship as an essential for the license has been adopted in eleven states;[1] in ten other states[2] foreign physicians must have taken out their first naturalization papers before being eligible for a license, and in five states[3] foreign physicians must have declared their intention to become American citizens. In Michigan and New York, in uncertain cases, a year's work in a medical school in this country must have been completed, while in Pennsylvania the foreign physician is required to have completed an internship in a hospital recognized by the licensing board.

These regulations, although representing a change of attitude on the part of state licensing boards, are still much more lenient than the requirements in countries abroad with which American physicians must comply. There is still the desire to welcome from abroad those who are properly qualified and who will become reputable and worthy members of their communities. The restrictions are necessary, however, to prevent the inpouring of those who are not properly qualified or who in other respects are undesirable. Under no circumstances should physicians from abroad be accepted unless their credentials have been carefully verified and unqestionable proofs obtained of identity.—*Jour. A. M. A.,* May 15, 1926.

Fundamental Data of Science Gathered in New Volumes.—The fundamental facts and figures upon which physical science is built have been brought together and issued for the use of the world in International Critical Tables, the first volume of which has just been issued by the National Research Council and the National Academy of Sciences.

Millions of experiments extending over years of time in the various laboratories of the world were necessary to produce the hundreds of pages of explanations and statistics that will be included in the five volumes of the completed work which are being compiled by the editors with the aid of specialists and experts here and abroad.

The first volume just off the press contains among other valuable information the accumulated data on no less than 9534 different chemical compounds, the new and old facts on radioactivity, and transmutation, astronomical and geodetic data and a comprehensive discussion of the most recent developments in the field of atomic structure, favorite speculative playground of physicists of the present moment.

Along with the international metric system and a listing of the seventy-four countries in which it is now compulsory are the local systems of weights and measures in use in twenty-five still conservative countries. The measures used by the Pharoahs of Egypt and the ancient Chaldeans may likewise be found side by side with their modern equivalent in feet and meters, gallons and litres.

Thousands of dollars and many hours of time will be saved the research workers of the present and the future by the use of this collection of necessary and essential data on a wide variety of allied subjects in one set of volumes.—*Science News Letter.*

Nerve Currents Heard on Radio Instrument.—The electric current that shoots along a nerve fibre has been detected by means of radio apparatus, according to Dr. E. D. Adrian, of Cambridge University, who described before a meeting of the Physiologcial Society his method of using a three tube instrument to make his delicate measurements.

It had long been known, he said, that the passing of messages down a nerve caused an electrical disturbance. But it had only been possible to record the effects from a large number of fibres at once, for example, the thousands of fibres from an eye, or to a muscle. The results obtained were therefore as confused as would be the superimposed records from all the telegraph wires between London and Manchester. Dr. Adrian's new apparatus makes it possible for the first time to obtain records in a rapidly moving photographic plate of the impulses passing along a single fibre.

In conjunction with Dr. Zottermann, a Norwegian neurologist, Dr. Adrian recorded the results of stimulating a sense organ connected with the brain by a single fibre. The sense organs in the skin which give information as to touch, pain, and temperature, are too near together for this to be easy. Those in the muscles subserving the socalled muscular sense are farther apart, and by stretching a frog's muscle it was found possible to stimulate a single one. The impulses were all of the same size, but as the muscle was stretched, their frequency was increased from ten to fifty per second. Differences of intensity are in fact transmitted through the nerves as differences of rhythm.

This is the first occasion on which the message passing along a nerve has been decoded, and the experiment opens up a new field of neurology, in the opinion of physiologists here. Within the next few years it should be possible to read the main types of messages entering and leaving the nervous system, and the time has been brought measurably nearer when it will be possible to record the actual events in the brain which are the physical correlate of consciousness.—*Science News Letter.*

Smell.—As Prof. Elliot Smith has often reminded us, primitive land animals lived in a world where perception must have been mostly dominated by the smells of things, says an editorial writer in the *Lancet,* April 24, 1926. In their evolutionary progress, vision and hearing became relatively more important. In the higher animals all three are well represented, but in man smell has not made anything like the advance of the other senses, and indeed it seems now to be in much the same place as it was in his remote ancestors. Associated with this primitive condition is the fact that the mind of man has great difficulty in dealing intellectually with the sense of smell and what it perceives. In the *Glasgow Medical Journal* for March, 1926, Dr. J. L. Halliday has an interesting discussion of the position. At present we have not got even a qualitative scale of smells, still less any means for their quantitative measurement. The sense seems to be fatigued extraordinarily quickly, which makes its measurement very difficult by the minimal perceptible dose method which is the only one available. Smells are individual, and no smell seems to have a clear relation to another smell. And while any smell may have the most vivid associations in the mind with other circumstances—evidently the useful state in primitive conditions—the human brain has not yet risen to abstracting smells, so that they can be associated by similarity with one another. There is hence no scale or spectrum of smells, and smells may be said to have no intellectual value. Interest is being taken in various quarters in this sad state of affairs; there is an occasional periodical *Osmics,* and Mr. E. E. Free has an article in the March issue of the *Forum,* and we may look forward with confidence to the time when human ingenuity will denominate smells as it has colors. It is after all not so very long ago that the color of blood could be described only as being blood-colored, just as nowadays we can get no further than saying that blood smells like blood. Though, to be sure, people realized that blood is not very dissimilar in color to some flowers thousands of years before they came to compare the smell of blood to the smell of anything else.

Health Heroes.—The Metropolitan Life Insurance Company has started the publication of a series of booklets on Health Heroes, written by Grace T. Hallock, formerly associate director of publications of the American Child Health Association, and C. E. Turner, associate professor of biology and public health, Massachusetts Institute of Technology. The first two booklets are on Louis Pasteur and Dr. Edward L. Trudeau. They will be followed by stories of Walter Reed and Jenner.—*Health News.*

In recommending an infant food —consider its nutritive value first

Cleanliness, digestibility, and palatability are also of importance, but without nutritive value any food would be useless as a body builder.

FOR the infant, breast milk furnishes all of the requirements mentioned. There is no need to seek further for a better food because no one has as yet been able to prepare a formula which can be considered anything other than a second choice.

As a breast milk substitute there is no better food for the infant than Eagle Brand Milk. For more than four years the largest child-feeding clinic in the history of the world has been maintained in the Near East, and Eagle Brand Milk has met every requirement for a complete milk food for the infants and older children throughout this period.

Reprints of clinical experiments with sweetened condensed milk will be sent upon request.

The Cost of Rearing a Child.—A statistical survey of the items entering into the cost of bringing a child to maturity was recently undertaken by the Metropolitan Life Insurance Company, and their findings have been published in the *Statistical Bulletin*. After a careful analysis of all items of expenditure, they present the following itemized statement for the cost of rearing a child to the age of eighteen years:

1. Cost of being born	$250
2. Food	2,500
3. Clothing and shelter	3,400
4. Education, minor items met by the individual family purse	50
5. Health	284
6. Recreation	130
7. Insurance	54
8. Sundries	570
Total	$7,238

This does not include major items of education, which amount to about $1,100, the cost of schooling provided by the community.

In round numbers, therefore, we may put the total cost of raising a child to age eighteen, in accordance with the data here collected, at $7,200. In this summary figure no distinction has been made for sex because the difference in the amounts for girls and boys is relatively small. This amount is believed to be a fair representation of the money expended by a family of the $2,500 income class in raising a child through its minority.

A Tuberculosis Clinic at the New York Hospital.—A department for the investigation and treatment of tuberculosis of the genitourinary tract has been established at the Urological Clinic (James Buchanan Brady Foundation), New York Hospital, 8 West Sixteenth Street. The tuberculosis clinic sessions will be conducted on Tuesday and Friday afternoons at two o'clock for adults and on Saturday mornings at nine o'clock for children. The purpose of the new department is not only the surgical treatment of tuberculosis of the genitourinary tract but also to supplement the treatment with those measures that have proved of value in the general treatment of tuberculosis such as rest, diet and hygiene together with heliotherapy, artificial light therapy and tuberculin where these are indicated. The tuberculosis department is under the direction of Dr. O. S. Lowsley, director of the urological clinic (James Buchanan Brady Foundation), New York Hospital. Dr. Stanley L. Wang will be associated with the department in carrying on the supplemental tuberculosis treatment.—*New York Medical Week,* May 15, 1926.

Tuberculosis Clinics Discover Many Other Physical Defects.—The diagnostic facilities offered by the Health Department's tuberculosis clinics, which are conducted on a strictly consultation basis with the family physician, are often responsible for the discovery of many nontuberculous diseased conditions or defects not previously suspected.

During the last calendar year, 226 nontuberculous conditions were found as follows: Diseases of lungs and air passages (nontuberculous), 146; diseases of heart and bloodvessels, 42; miscellaneous, 33.—*Health News.*

After all the most important thing is to relieve the distressing symptoms of digestive disorders first and then apply the systematic remedies for proper correction of functional defects. Do you know that thousands of doctors recommend six (6) Bell-ans dissolved in a glass of hot water for immediate relief in digestive disorders?

Bell-ans gives results; that is why it is now universally used.

Pruritus of the Perineum

and other Skin Irritations

are promptly relieved by local applications of

K-Y Lubricating Jelly

The pronounced cooling and soothing action of this effective lubricant-emollient-protective is at once manifest in the majority of cases.

The best results are obtained if the parts are washed with tepid water before each application.

HEADACHE AND NEURALGIA

are relieved by rubbing in

K-Y ANALGESIC

"The Greaseless Anodyne"

Apply a moist, hot towel to the painful area before rubbing in K-Y Analgesic. "A safe harmless measure that gives results most of the time."

Both K-Y Lubricating Jelly and K-Y Analgesic are non-greasy and easy to wash off with water, making them pleasant to use.

Johnson & Johnson New Brunswick, N. J., U. S. A.

NEW PRODUCTS

Vemo Deodorant Powder

(Formula on application)

This preparation is designed for professional recommendation in those cases where objectionable body odors persist in spite of frequent bathing, change of clothing, etc.

It may be used freely in the axillary and perineal regions and on the feet without the slightest caustic action upon the skin.

Fastidious patients appreciate the fact that it is more than an odor-replacer. Not a perfume.

ANNOUNCING—

Isacen "Roche"

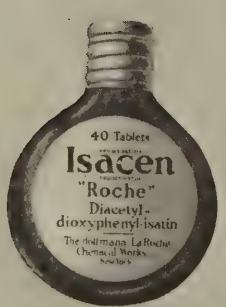
A New and Scientific Laxative

WE take both pride and pleasure in announcing to the profession a new chemical substance, evolved in the Roche Scientific Laboratories, which exerts a very fine laxative action in minute dosage, yet is non-toxic—in fact perfectly harmless.

This new substance is diacetyl-dioxyphenyl-isatin, a synthetic derivative of Indigo. It is a white crystalline powder, odorless and tasteless. It passes through the stomach unchanged and does not become active until it reaches the proper site for action, the intestine.

No renal or hepatic irritation need be feared from the use of Isacen, for this new purgative substance is not absorbed. It is entirely eliminated by the intestine—not even a trace of it can be found in the urine. Hence, Isacen can be taken with safety over periods of time even in those cases where there is a liver or kidney derangement.

Isacen is marketed in the form of small tablets each containing 1/13 grain of the substance. As is the Roche custom, Isacen was thoroughly investigated both pharmacologically and clinically before its formal announcement to the profession.



Literature and complimentary supply for trial on request

Calcium and Phosphorus

The profound physiologic importance of calcium and phosphorus, especially in the so-called wasting diseases, is becoming increasingly evident, and the best form of calcium and phosphorus for administration is unquestionably calcium glycerophosphate.

ESKAY'S NEURO PHOSPHATES

contains calcium and phosphorus in the form of glycerophosphate, is rapidly absorbed and does not cause gastrointestinal irritation on long-continued use, as do the usual calcium salts.

Today millions "Eat to Keep Well"

Physicians are teaching the public important principles of diet

TO the physician must go most of the credit for the contemporary interest of the layman in right eating. The medical profession as a whole has been untiring in its efforts to school the public in certain simple but very important principles of nutrition. The great interest today in fresh fruits and vegetables is just one indication of the success obtained.

As one food in a correct diet, fresh yeast is recommended by physicians everywhere. And though Fleischmann's Yeast is in no sense a medicine, it has several qualities which recommend it as a corrective for certain common ailments.

In cases of constipation, it increases the bulk and moisture of the faecal masses, tending to soften them, and, especially when drastic cathartics are undesirable, it acts as a gentle though effective bowel regulator.

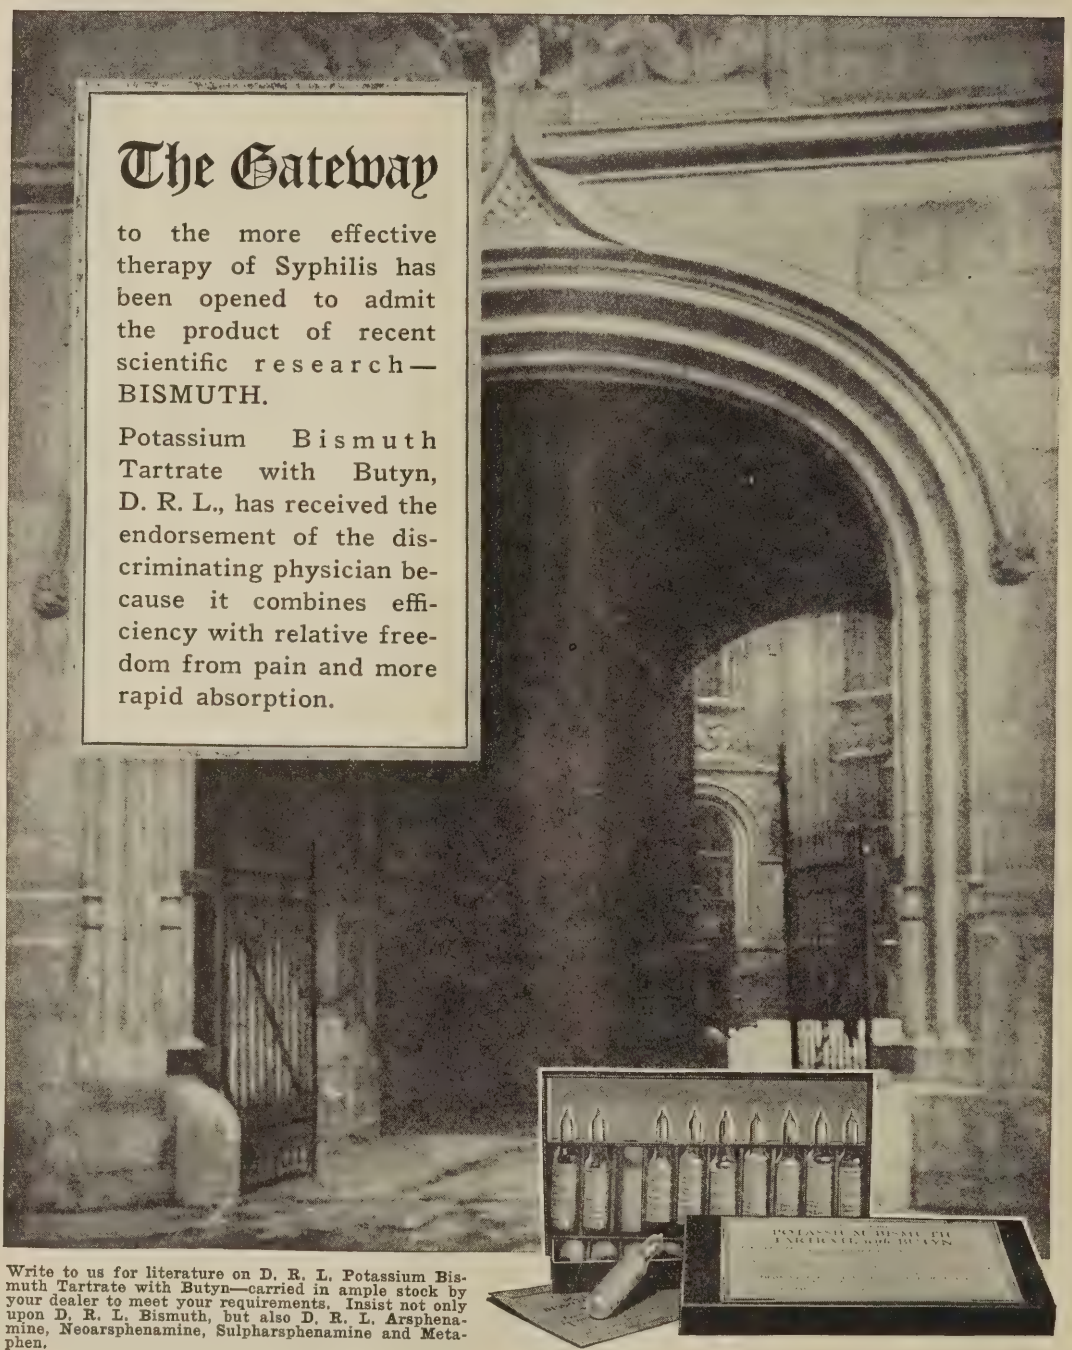
Yeast also has its value when digestion is disturbed; it frequently can be eaten to advantage when other foods cause trouble. It is remarkably effective for boils and other skin disorders, as all medical men know. And it has a tonic effect when vitality is low.

* * *

FLEISCHMANN'S YEAST may be eaten in a number of ways, preferably before meals: in fruit juices, water or milk, for example—spread on crackers—or just plain, nibbled from the cake.

A copy of our latest booklet on Yeast, for physicians, will be sent to you on request. It contains authoritative scientific matter on the subject.

The Fleischmann Company, Dept 252, 701 Washington Street, New York, N. Y.



The Gateway
to the more effective therapy of Syphilis has been opened to admit the product of recent scientific research—BISMUTH.
Potassium Bismuth Tartrate with Butyn, D. R. L., has received the endorsement of the discriminating physician because it combines efficiency with relative freedom from pain and more rapid absorption.

Write to us for literature on D. R. L. Potassium Bismuth Tartrate with Butyn—carried in ample stock by your dealer to meet your requirements. Insist not only upon D. R. L. Bismuth, but also D. R. L. Arsphenamine, Neoarsphenamine, Sulpharsphenamine and Metaphen.

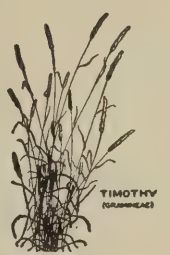
The New Method of Hay Fever Treatment



THE tendency is increasing, in recent years, to give a greater number of doses, of higher protein content, at shorter intervals (12 to 48 hours).

In Hay Fever Treatment, 15 doses have come to be regarded as the minimum that should constitute a treatment, while some authorities recommend 20 doses or more, as indicated, and treatment being continued through the hay fever season.

The Mulford Pollen Extracts are supplied in such forms and strengths as afford greatest convenience in measuring dosage and making injections.

Easy to Use for General Practitioner or Specialist

Mulford Pollen Extracts, for the four principal pollen groups (ragweed, timothy, lamb's quarters and wormwood) are supplied as follows, in measured, individual doses and in ready-to-use containers:

15-dose Treatment Package (Doses 1 to 15)
First Series Package (Doses 1 to 5)
Second Series Package (Doses 6 to 10)
Third Series Package (Doses 11 to 15)
Fourth Series Package (Doses 16 to 20)
Also in 5 cc vials.

Mulford Pollen Extracts are the specific pollen proteins in refined form, accurately standardized in terms of protein units (one protein unit is comparable to four pollen units).

They are stable in solution, thus avoiding all inconvenience of diluting or mixing before use.

Mulford superior quality is typified in these products—in the specificity and uniform strength of the extracts and in the convenience of the packages.

ANGIER'S EMULSION

In the treatment of measles, whooping cough and convalescence from acute infectious fevers, Angier's Emulsion protects the patient against dangerous respiratory after-effects, aids digestion and promotes nutrition.

ANGIER'S is pleasant to take, will not upset the stomach, and the perfectly emulsified oil maintains proper elimination, thereby insuring a healthy intestinal tract and freedom from auto-toxic effects.

If you have a case where you would like to try some samples, we will send them, charges prepaid, on request.

DIABETES, TOXEMIA AND DIABESAN

Dr. C. A. M. of Atlantic City, New Jersey, writes us under date of January 20th, 1926, as follows:

"Gentlemen:

Kindly send me one thousand (1000) tablets of Diabesan. I am using your Diabesan in many cases of intestinal toxemia and diabetes with surprising good results.

Enclosed please find check.

With my best regards,

Yours,

(Signed) C. A. M., M.D."

Diabesan is efficacious and harmless. There is no danger of an overdose.

Anusol

Trade Mark

Suppositories

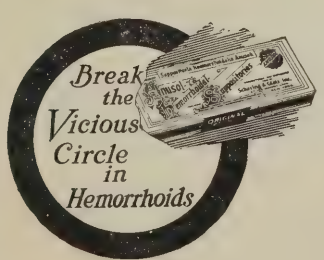
Compared with the recorded age of Hemorrhoids as a disease known to physicians,

ANUSOL SUPPOSITORIES might be termed mere youngsters.

For in Deuteronomy XXVIII, 27, Moses is quoted as having threatened the misguided ones among his followers with:
"the Lord shall smite thee with the botch of Egypt and the *emerods*"—

While ANUSOL SUPPOSITORIES have *only* a thirty-year record as the leading non-surgical remedy in Hemorrhoids.

Still, thirty years of steadily increasing and now very extensive patronage, including that of the most discriminating physicians, surely is adequate testimony of unusual merit.



Your Wholesaler will Promptly supply you.

PARKE DAVIS AND COMPANY

RABIES VACCINE

(Cumming)

THE importance of preventing rabies is fully appreciated by the medical profession for the reason that not a single cure of a well authenticated case of human rabies has ever been reported.

The prompt employment of Rabies Vaccine is imperative for the safety of the patient. Rabies Vaccine (Cumming), P. D. & Co., is a product that represents the antigenic principle of rabies virus, but since it contains no living virus it can be administered without risk of precipitating an attack of rabies. The doses are not numbered, for they are all alike; 2 cc. of a harmless vaccine by hypodermic injection; no more exacting technique than that.

Rabies Vaccine (Cumming), P. D. & Co., is made by the method devised by Dr. J. G. Cumming. A one per cent suspension of rabic brain tissue (from rabbits dying of rabies induced by an injection of fixed virus) is dialized against running distilled sterile water until the infectivity of the virus is destroyed. The safety of the finished product is assured by injection beneath the dura of rabbits and subcutaneously in guinea-pigs and mice. Sterility tests are also utilized to insure freedom from bacteria. The vaccine is standardized by weight so that 2 cc. of suspension, the contents of one of the syringe containers, contains sufficient material for one injection for an adult.

The safety and efficiency of Rabies Vaccine (Cumming), P. D. & Co., has been amply demonstrated by its employment in at least ten thousand cases of bites from rabid animals. The usual treatment consists of twenty-one injections—one injection daily for three weeks. A shorter course—one of fourteen injections only—suffices when the wound is only a slight scratch on the hands or lower limbs.

Rabies Vaccine (Cumming), P. D. & Co., is supplied in packages of seven 2-cc syringe containers, complete, with needles, each syringe holding one dose. Orders for a 21- or a 14-dose treatment should be sent direct to Detroit (the home office) or the nearest branch or depot.

FIBROGEN ORAL
MERRELL

ADMINISTERED orally, Fibrogen, in 3 c. c. dosage, controls hemorrhage in every part of the body within 15 minutes.

Used 15 minutes before operating, Fibrogen Oral not only prevents hemorrhage, but also assures the surgeon of an almost bloodless field.

Fibrogen, or *tissue fibrinogen*, is normally present, as a definite chemical compound, in all body tissues and is an essential element in clot formation.

Fibrogen Subcutaneous is also available, in ampoule form, and is equally effective. Its effect is slower, but more prolonged, lasting from 8 to 10 hours.

The Management of an Infant's Diet

Mellin's Food—A Milk Modifier

In the selection of a milk modifier the following factors are worthy of serious consideration:

Quality of materials employed in the making of the product.
Care exercised in every step of manufacture.
Uniformity of composition of the finished product.
Anticipated results—based upon the character of the contained food elements and records of successful use.

During the long period that has elapsed since the introduction of Mellin's Food to the medical profession, there has been ample opportunity for physicians to judge how well Mellin's Food measures up to the above-stated outstanding points of importance. That the judgment passed has, in the main, been favorable is clearly indicated by the high standard of excellence accorded to Mellin's Food by physicians generally and particularly by doctors whose practice embraces the field of pediatrics.

Mellin's Food Co., 177 State Street Boston, Mass.

Information to the New York Visitor

AS a visitor to New York, you have a problem: "Where shall I stop in comfort and convenience—without extravagance?"

We answer—at the Martinique.

A modern, fireproof building, in the very centre of all business activity, the Hotel Martinique offers unusually comfortable accommodations at unusually economical rates—rooms as low as $2.50 per day.

Special restaurant service—most moderate prices.

We invite investigation. On your next visit, stop in and let us prove that you can live right at the right price while in New York.

THE JEFFERSON MEDICAL COLLEGE

OF PHILADELPHIA

ONE HUNDRED AND SECOND ANNUAL SESSION BEGINS SEPTEMBER 22, 1926, AND ENDS JUNE 3, 1927

FOUNDED 1825. A CHARTERED UNIVERSITY SINCE 1838. Graduates number 14,625, nearly 6,000 of whom are active in medical work in every State, and many foreign countries.

FACILITIES: Well equipped laboratories; separate Anatomical Institute; teaching museums; free libraries; unusual and superior clinical opportunities in the Jefferson Hospital, Jefferson Maternity, and Department for Diseases of the Chest. A sixteen-story addition to the Jefferson College Hospital, containing the new Clinical Amphitheater, the Maternity Department and the new Clinical Laboratories was opened in November, 1924. These buildings are all owned and controlled by the College. Instruction privileges in six other hospitals.

FACULTY: Eminent medical men of national reputation and unusual teaching ability.

ADMISSION: Not less than two College years leading to a degree in science or art, including specified science and language courses. Preference is given to those who have completed additional work.

APPLICATIONS should be made early.

Dioxogen

A superior solution of Hydrogen Peroxide for surgical and medical use

Stronger than the U. S. P. standard, of much greater purity and with but a fraction of the acid permitted by the U. S. P.

DIOXOGEN is free from the objections commonly found in Peroxide of Hydrogen.

Of uniform quality, containing no acetanilid, DIOXOGEN is practically stable at all ordinary temperatures.

DIOXOGEN represents the best to be found in the H_2O_2 solutions.

Agar Bulk of No Consequence In Emulsions of Liquid Petrolatum

To get the equivalent of a U. S. P. normal dose of agar would require one pint of the emulsion at each dose.

THE American Medical Association, through its Chemical Laboratory, recently analyzed leading emulsions of liquid petrolatum. None was found with more than 1.5% of dried agar.

Our own research, confirmed by the findings of the American Medical Association, has demonstrated that the agar is of no consequence in emulsions of liquid petrolatum.

Plain Nujol has proven the most satisfactory in the majority of cases. But a few patients are unable to take plain liquid petrolatum because of an aversion to any oily product. Such patients find the emulsion, Cream of Nujol, smooth, creamy, pleasantly flavored and agreeable to take.

Unlike other leading emulsions analyzed by the American Medical Association, Cream of Nujol contains no benzoate of soda or other artificial preservative.
